THREE STEPS IN THE TUBERCULOUS PROCESS IN CHILDREN.

By DAVID BOVAIRD, Jr., M. D.

As an introduction to the paper which I have the honor of presenting this evening, it seems proper to state that our facts are drawn from observations made in the autopsy room and wards of the New York Foundling Hospital. The children under the care of that institution range, as a rule, from birth to five years in age. Occasionally, for some adequate reason, a child is kept beyond the latter age, but the number of older children is very small. Between five and six hundred of the children are regularly kept within the institution itself; a hundred and sixty are at the country home; the remainder, about thirteen hundred, are cared for by nurses living in various parts of the city and its suburbs. Infants below the age of one year are nursed, either in part or in whole. Beyond that age the children are artificially fed. Inasmuch as more than three fifths of the children are cared for outside the institution itself, in the humblest homes of the city, it seems fair to assume that whatever peculiarities in the life history of the remainder might be due to the surroundings and regulations of institution life are fairly neutralized, and the conditions found from observation of the material met with in the hospital may doubtless be considered as fairly representative of those prevailing among the children at large in this community.

Turning now to our subject, we take up:

1. The Primary Lesion in Tuberculosis in Children. — In 1891 Northrup published in the New York Medical Journal an article entitled Tuberculosis in Children: Primary Infection in the Bronchial Lymph Nodes. In a series of a hundred and twenty-five autopsies on tuberculous subjects he had found thirteen cases in which the tuberculous lesion was confined to the bronchial lymph nodes; nine in which the tubercles of the body were limited to the bronchial nodes and lungs, the latter containing only discrete, gummy, miliary bodies, while the bronchial nodes were far advanced in the degenerative process; forty-two cases of general tuberculosis in which the only cheesy masses were in the bronchial lymph nodes; twenty cases of general tuberculosis in which the oldest lesion was in the respiratory tract.

Of the series of a hundred and twenty-five cases, he considered eighty-eight as examples of primary infection of the bronchial lymph nodes, and three of primary infection of the mesenteric lymph nodes; thirty-four were indeterminate.

This paper having served to focus attention upon the subject, since that time (1891) every case of tuberculous occurring in the hospital has been carefully searched for further evidence along this line. The contribution made this evening is based upon the records of a further series of seventy-five autopsies on tuberculous subjects in the same institution. In passing, we may note that these seventy-five cases of tuberculosis were found in a total of six hundred and sixty-five autopsy records, a proportion of eleven per cent.

Of this total of seventy-five, four patients showed a tuberculous lesion of the bronchial nodes alone. Of these, one died at the age of three years, of laryngeal diphtheria requiring intubation; one at the age of four years, of a succession including whooping-cough, measles, diphtheria, and gangrene; the third, at the age of five months, after an illness of a month, due to otitis media; the fourth, when four years old, of an acute purulent peritonitis. In none of these cases did the tuberculous lesion stand in direct relation to the cause of death. In no other cases was the tuberculous lesion confined to one particular anatomical area (exception). In one case the tuberculous lesions were confined to the bronchial and mesenteric lymph nodes, there being no indications to determine the question of priority. In no case were tuberculous lesions of the intestines or mesenteric nodes discovered without accompanying tuberculous lesions of the lungs and bronchial lymph nodes. Only in the four cases above cited can we put the finger immediately upon the primary lesion, yet in the great majority of cases we can at least determine the tract within which the primary lesion must have lain. There are four avenues or portals by which the tubercle bacillus may be admitted to the system: 1. The placenta. 2. Wounds of the surface of the body. 3. The intestinal tract. 4. The respiratory tract.

In none of our cases do we find evidence of the entrance of the tuberculous infection by either of the two first routes. The question lies between the intestinal and respiratory tracts. Studying our cases with reference to this question, we find the tuberculous lesions in bronchial nodes alone, 4 cases; bronchial nodes and lungs, 16 cases; bronchial nodes, lungs, and bones, 3 cases; bronchial nodes and bones (without lungs), 1 case; bronchial nodes, lungs, and other viscera (general miliary tuberculosis), without lesion of intestines or mesenteric nodes, 20 cases; bronchial nodes, lungs, etc. (general miliary tuberculosis), with lesions of intestines or mesenteric nodes, advanced changes (cavities) being in the lungs, 16 cases; bronchial nodes and mesenteric nodes or intestine with slight changes in lungs (miliary tubercles), 7 cases; bronchial nodes, lungs, etc. (general miliary tuberculosis), without note of condition of intestines or mesenteric nodes, 7 cases; bronchial nodes and mesenteric nodes without other tuberculous lesions, 7 cases — total, 75 cases.

That is, in no case in which tuberculosis was present...
in the body did we fail to find tuberculous lesions of the bronchial nodes. In the twenty cases of general miliary tuberculosis without lesion of the intestine or mesenteric nodes, not only can we infer that the respiratory tract was the portal of entry, but the inference is supported by indubitable evidence in the character of the tuberculous lesions present in the various organs, the advanced tuberculous changes, caseous or calcareous degeneration or cavities, being present in the bronchial nodes or lungs; while in the other viscera we find either fresh miliary tubercles alone or associated with other evidences of recent processes, such as the fibrinopurulent exudate that so often accompanies tuberculous menigitis. Exception may here be made of the cases in which the bones were involved. The relative age of lesions of the bones and soft parts it is not easy to calculate, but when we find tuberculous lesions of the bones associated with tuberculosis of the bronchial lymph nodes or lungs, and no tuberculous lesion elsewhere, it is not difficult to judge as to the original seat of disease apart from the gross appearances of the lesions.

Likewise, in the cases in which we find caseous mesenteric glands accompanying the presence of tuberculous cavities in the lungs of children who have not yet acquired the ability to expectorate, it seems only a fair inference that the lesion of the intestine has probably been caused by the swallowing of bacilli coughed up from the affected parts of the lungs, but not expectorated.

We have, therefore, in sixty of our seventy-five cases evidence that the entrance of the tuberculous infection took place through the respiratory tract, the primary lesion being either in the lungs or bronchial lymph nodes. In eight cases the lesions of the bronchial and mesenteric lymph nodes were so nearly alike that the question of priority could not be determined. In seven cases the records stated distinctly that the bronchial lymph nodes were found tuberculous; but, as there was no clear statement of the examination of the mesenteric nodes or intestine, we have not cast them in either scale. In not a single case was there definite evidence of infection by the intestinal tract alone (exception noted). We have already cited one case in which both bronchial and mesenteric lymph nodes were found caseous without other tuberculous lesions. It would seem that in this case the bacilli must have been admitted both to lungs and intestines at about the same time.

Briefly summarized, therefore, we have: Infection by respiratory tract, 60 cases; infection by either respiratory or intestinal tract, 8 cases; infection by respiratory tract (records incomplete), seven cases, total seventy-five cases.

**Early Clinical Manifestations.**—In seeking to make definite statements on this point, we find that we have a much more difficult problem to deal with than that of determining the primary seat of disease from pathological investigation. Some few points are, however, fairly clear.

*This and the three following plates are reproduced by permission from Dr. W. P. Northrup's article, Tuberculosis in Children; Primary Infection in Bronchial Lymph Nodes, *New York Medical Journal*, February 21, 1891.
In the cases in which the bronchial nodes alone were affected no suspicion of the presence of tuberculosis was entertained until the lesion was discovered at autopsy. The children died of intercurrent disease, bearing no relation to the affection of the bronchial lymph nodes. Until the intervention of other disease there had been nothing to call special attention to the condition of the children or mark them as sickly in any way. We may go farther and say that even had examination been made for the presence of such tuberculous foci, it is extremely improbable that any evidence of its presence would have been detected. In our experience the cases in which the presence of enlarged bronchial or mediastinal glands can be demonstrated form but a very small percentage of the cases in which they are actually present. The physical signs usually given as indicating their presence we regard as rarely sufficient to serve practical purposes. Dullness over the upper part of the sternum, even if present, is more often due to the persistence or enlargement of the thymus than to the presence of enlarged bronchial or mediastinal nodes.

The presence of a venous hum heard over the manubrium on hyperextension of the head is a sign we have rarely found of any value. The same is true of modifications of the respiratory murmur in the interscapular region. It often reflects on the deep situation of these nodes—that behind them we meet with the solid vertebral column; that the hollow tubes of the trachea and bronchi run between them, while in front they are normally overlapped by aercrated lung—the difficulties in the path of physical diagnosis are apparent.

In the services of Dr. O'Dwyer and Dr. Northrup at the Foundling Hospital the diagnosis of tuberculous bronchial lymph nodes has never been made. In fact, the physical signs above mentioned can be of value only in the presence of great masses of enlarged nodes, a condition rarely met with in children at the ages with which we are dealing. It may here be in point to give in detail the ages of the cases comprised in our tables:

Birth to one year, 27; one to two years, 15; two to three years, 6; three to four years, 15; four to five years, 6; six to seven years, 1; seven to eight years, 1; age not given, 4—total, 75.

Fifty-six per cent. of our patients were, therefore, below the age of two years.

Tuberculosis, long latent in the bronchial glands, may be roused and disseminated under the influence of the intervention of an acute infectious disease, the symptoms of the latter entirely masking the presence of tuberculosis.

To illustrate this point, we may quote the following cases:

Case I.—Girl, aged three years. For four months she had had tuberculous disease of the tarsus. On March 22, 1896, she developed measles, which ran a normal course for a week. She then developed diphtheria (March 29th), and was given antitoxine. While recovering from this, colitis supervened, the temperature assumed the hectic type, and the child failed steadily, dying April 10th. Total illness, nineteen days. The autopsy showed evidences of diphtheria in the larynx, and caseous bronchial nodes and miliary tubercles in the lungs, with a bronchopneumonia of the posterior portions of both lungs. A deep congestion of the colon was the only intestinal lesion.

Case II.—Boy, aged eight months. On January 5, 1897, he developed diphtheria. On January 8th, three days later, he developed bronchopneumonia, and died on the 11th. Illness of six days. The autopsy showed caseous bronchial glands, a small cavity in the left lower lobe surrounded by numerous caseous nodules, with miliary tubercles scattered throughout the lungs. The colon showed a number of small ulcers. The mesenteric glands were enlarged but not tuberculous.

It is hardly credible that the tuberculous process could have made such advances in the six days of illness from the diphtheria, yet up to the onset of that disease the child was considered well.

Tuberculosis in infants, in its clinical manifestations, is usually an acute, not a chronic, disease; often the outbreak and course are astonishingly rapid. Again we may refer to our cases for examples.

Case III.—Girl, aged eleven months. Until a week ago she was in the hospital perfectly well, and was sent out to nurse. Was returned in collapse, and died the following morning. The autopsy showed a mass of caseous bronchial nodes; many miliary tubercles in the lungs, liver, and spleen. The intestines and omentum were matted together by adhesions and filled with miliary tubercles. The Falloppian tubes were greatly distended by caseous material.

Case IV.—Girl, aged two years. She had measles in January, 1897. Afterward she was very pale, but seemed fairly well. On July 1st she was taken sick with diarrhea. On July 3d she was brought to the hospital. Temperature was 105° F.; abdomen distended and very tender; spleen felt; extremities cold; constant diarrhea; pectechial eruption on forehead and trunk. On July 4th she died, after four days' illness. The autopsy showed general miliary tuberculosis of the lungs, hemorrhages in the ascending colon, and enlarged and tuberculous mesenteric nodes.

Searching the records of our cases for early evidences of the invasion of tuberculosis, we can find only two of importance.

1. Progressive emaciation, not explained by any other disorder.

2. Continued elevation of temperature similarly conditioned.

Progressive emaciation (marasmus) in the early months of life, without demonstrable lesion, is, as we all know, very common. Beyond the age of six months it is uncommon. In fact, it has become a recognized practice that any child over the age of six months presenting symptoms of marasmus should be carefully watched and examined for some explanation of the
wasting. Frequently, tuberculosis is the cause finally determined.

Persistent fever, not otherwise explained, is also very suggestive. Under the age of two years it is all the more suggestive by reason of the relative rarity of typhoid fever at that age. In fact, we need hardly put the age limit at two years, for thus far we have never met with typhoid fever in the Foundling Hospital. The temperature found in cases of general tuberculosis in children varies greatly. It may run as high as 103°–104° F., or may not exceed 100°–101° F. throughout the course of the disease. We may even meet with cases which run their course without fever, or even with subnormal temperatures.

If local signs are to be found, we must seek them in the lungs. In our seventy-five autopsies the lungs were involved in sixty-five cases.

The lesion varies from scattered miliary tubercles to diffuse consolidation of the whole lobe or an entire lung, with caseous degeneration and cavities in the final stages.

The early manifestations arise, as a rule, from disseminated foci in the lungs. The physical signs are confined to rales, usually subcrepitant or coarse. Only in the later stages do we expect to find evidences of consolidation. We shall not at this time attempt to enter into the difficult subject of the differential diagnosis between simple and tuberculous bronchopneumonia.

We must frankly admit the insufficiency of the points suggested for the diagnosis of the invasion of tuberculosis. They may suggest the possibility of the presence of tuberculosis; they do not differentiate it.

A number of tuberculin tests which have been made in the Presbyterian and the Foundling hospitals have failed to give satisfactory results, but the number is too small for any final judgment. The truth is that the great majority of cases of tuberculosis in young chil-

Fig. 2 (natural size).—Section through a large mass of cheesy nodes grouped about the bifurcation of the trachea and the root of the lung, also cheesy masses reaching into the lung. Two bronchial nodes show beginning softening at their centres, and below them there is one smaller node containing a chalk mass.
children die without recognition, often without suspicion of the presence of tuberculous lesions. The course of tuberculosis in children is most often confused with chronic bronchopneumonia or enterocolitis.

**Complications and Terminal Lesions.**—We find these either in the extension and intensification of the local process in the lungs and bronchial lymph nodes, or with, the child dying within a few minutes from suffocation.

More commonly the progress of the disease within the lungs leads to the formation of large areas of tuberculous consolidation and finally cavities, the child dying of exhaustion. Cavities were found in twenty-five cases of our series.

In some cases the softening and formation of abscesses in the bronchial lymph nodes have led to death either by extension of the process to the lung or by rupture of the abscess into either the esophagus or the trachea. Recently an example of the latter accident was met in the general diffusion of the tuberculous infection.

The final stage is most often reached by the dissemination of the tubercular infection. We find a general miliary tuberculosis recorded in fifty-two cases.

We know little of the process by which this dissemination is brought about. Evidently it may occur by the communication of a caseous nodule in the bronchial
nodes or lungs either with the blood-vessels or lymphatics. Whether it is by rupture into a blood-vessel or whether, after the bronchial nodes are fully charged, bacilli may be able to pass through them, we do not know. At any rate the dissemination is usually general and complete. Thus we find the kidney involved (meaning the presence of miliary tubercles) in 13 cases; spleen, 37 cases; liver, 28 cases; heart, 1 case; pericardium, 2 cases; peritoneum, 6 cases; adrenals, 2 cases; brain, 22 cases.

The last is the important item. In twenty-two cases we found tuberculous meningitis. In some few cases this was limited to the presence of miliary tubercles; in most, the miliary tubercles were accompanied by more or less plastic exudation, especially at the base of the brain. We may safely say that in all these cases the meningitis was the direct cause of death.

In addition to the complications thus far mentioned, we need only say that in two cases, where the chief lesion was confined to the bones and was accompanied by prolonged suppuration, we found extensive waxy degeneration of the viscera.

In all but two cases meningitis was either a part of a general miliary tuberculosis or was accompanied by advanced changes in lungs—hopeless.

To summarize briefly the points we have endeavored to make:

1. The primary lesion of tuberculosis in children is regularly in the bronchial lymph nodes or lungs. Combining Northrup’s series with those described in this paper, we have:

<table>
<thead>
<tr>
<th></th>
<th>Northrup</th>
<th>Baird.</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Infection by respiratory tract (lungs or bronchial nodes)</td>

</tbody>
</table>

2. As to early manifestations of tuberculosis in children, these are extremely indefinite and uncertain.

a. Tuberculous infection of the bronchial lymph nodes, as a rule, can not be diagnosed.

b. Latent tuberculosis is often roused and disseminated by the invasion of another disease (infection), such as measles, diphtheria, etc., the presence of tuberculosis not being suspected.

c. The common type of tuberculosis in children is acute miliary tuberculosis—it may occur in well-nourished infants.

d. The course of tuberculosis is most often confused with chronic broncho-pneumonia or enterocolitis.

e. The early manifestations are progressive emaciation, fever, and the presence of râles over the lungs. These are insufficient for purposes of distinction.

3. The terminal lesions include—

a. Extension of the tuberculous process in the bronchial lymph nodes and lungs, resulting in the formation of abscesses, cavities, etc.

b. Diffusion of the tuberculous infection, constituting acute miliary tuberculosis, the principal viscera being affected in the following order: Spleen, liver, brain, kidney, heart. The involvement of the brain is most important, the meningitis being regularly fatal.

c. When bone is involved and there is prolonged suppuration, waxy degeneration of the viscera may occur.

SHADOWGRAPHS OF THE INTESTINAL VILLUS OF THE CAT.
By J. W. Hartigan, A.M., M.D., F.R.S. Lond.,
Professor of Biology in the West Virginia State University, Morgantown.

I present herewith one photomicrograph and two projection shadowgraphs of the intestinal villus of the cat.

These specimens were prepared by the celloidin method and stained with cosin and hæmatoxylin.

The specimens are interesting on account of the marked superiority of the shadowgraphs over the ordinary photomicrograph in point of detail.

The large images were thrown upon a screen by the projection microscope at a distance (focal) of fifteen feet and six inches, and the image then photographed with a camera obscura, with the accompanying result.

From this negative transparencies are made which are thrown upon the screen, at the same distance, by the lantern attachment, producing images characterized by greater brilliancy than is possible with the microscopic attachment. These images are then photographed, producing photographs with better detail than is possible with the microscopic treatment alone.

For structures—nerve cells, blood-corpuscles, and tissue elements—too small to come well within the focal distance of the objective of the projection apparatus, photomicrographs of the ordinary sort are made, the negatives of which are used directly by the projection microscope as original objects for screen images to be photographed by the camera obscura; or these photo-
A handsome method of preserving, in photographs, the histological structure of animal and vegetable tissues with an accuracy and amplification not possible with the usual laboratory methods. Even the most nearly perfected and improved camera lucida in the hands of an artist microscopist is in no wise a competitor in record accuracy. A glance at this villus will show the incomparable superiority of the method over those used to produce the most elaborate illustrations to be found in the proudest text-books of our time.

ON THE IMPORTANCE OF AN OPERATION IN THE FIRST STAGE OF THROMBOSIS OF THE SIGMOID SINUS (FOLLOWING ACUTE PURULENT OTITIS MEDIA), WITH A REPORT OF THREE CASES,

By Gorham Bacon, M.D.,
Professor of Otology in Cornell University Medical College, New York.

Mr. President and Gentlemen: I wish to call your attention this evening to the importance of operating early in cases of thrombosis of the sigmoid sinus, of otitic origin, and to report three successful cases which came under my observation.

Case I. Acute Purulent Otitis Media, followed by Inflammation of the Mastoid Cells and Thrombosis of the Sigmoid Sinus; Operation; Recovery.—The patient, Harry K., seven years old, had had a chronic discharge from the right ear for some time, and a year ago I removed the remnant of the drumhead with the careful ossicles. This was followed by a cessation of the discharge. On January 17, 1898, he had an earache on the left side, following an attack of amygdalitis. The pain continuing, I was called in by the family physician to see him on January 19th. At that time the inner end of the external auditory canal was so swollen that it was difficult to see the drumhead. Chloroform was administered, and I incised the membrana tympani and also the swollen walls of the canal. Leeches were applied just in front of the tragus and over the mastoid region, as there was considerable tenderness on pressure over the mastoid process. The ear was syringed every two hours with a warm boric-acid solution, except that twice during the day a bichloride solution was substituted for the boric-acid solution. The Leiter coil was also applied.

January 20th.—Less pain. A sticky yellowish discharge appeared. The patient had some elevation of temperature, and the pulse was 115 to 120.

22d.—The patient seemed to be doing well until today, when the temperature at noon was 103.8° F., pulse 140. At this time he was very dull and inclined to sleep. The ice coil had been kept on for forty-eight hours, and was then removed. He had no pain to speak of, except tenderness on pressure over the mastoid cells.

5 P. M.—Patient etherized, and, assisted by Dr. Townsend and Dr. Whiting, I made the usual incision over the mastoid process and opened the cells, removing softened bone and granulations, but very little pus. An opening was made into the antrum and the cells were thoroughly removed to the tip. The bony wall covering the sigmoid sinus was removed, and the sinus seemed to be normal in appearance. Before the operation the temperature was 104.3° F. in the rectum, and two hours later 102° F.

23d.—The temperature again rose to 104.4° F. (rectal) at noon to-day. The patient was seen in consultation to-day with Dr. Starr at 6 p. m., and at that time seemed much brighter and improved in every way, and at 11 p. m. the temperature had fallen to 100.8° F. Calomel was given at this time, and was also administered three days previously.

January 24th.—The temperature gradually rose

* Read before the Society of Alumni of Bellevue Hospital, April 5, 1899.
again, and at 9.45 A. M. the patient had a chill lasting twenty minutes, when the temperature was taken and recorded at 103.1° F. The patient after the chill was stupid and drowsy, and a diagnosis of sinus thrombosis was made. There was considerable oedema about the tip, especially in the soft tissues posterior to it.

3 P. M.—Again assisted by Dr. Townsend and Dr. Whiting, I enlarged the incision which I had previously made in the mastoid region by carrying the incision forward over the auricle and thus dividing the anterior temporal artery. At the lower portion of the wound I carried the incision directly backward. I then removed sufficient bone to examine the dura in the middle cerebral fossa, but found no pus over the tympanic roof. I then cut away with rongeur forceps sufficient bone to uncover the sigmoid sinus for a space of two inches, in order to be able to control the hemorrhage when incising the sinus. The bone was found soft in the direction of the jugular bulb, posterior to the mastoid tip.

The outer and anterior wall of the sinus seemed normal in appearance in the upper portion, but in the lower portion, near the bulb, it was hard and tough. While firm pressure was made over the lower portion of the sinus, an incision was made with a scalpel into the upper portion. At this point there was a free and instantaneous flow of blood, which was easily controlled by plugging with iodoform gauze. In the lower portion not only was the outer wall found dense, but, after an incision was made, the blood flowed much less slowly, so that it was necessary to remove a soft parietal clot with a curette in order to reestablish the blood current. A plug of iodoform gauze was applied, and the wound filled with strips of iodoform gauze over which several layers of bichloride gauze were laid. Then absorbent cotton and a bandage were applied.

During the operation it was necessary to administer strychnine, and immediately afterward cinemata of the normal saline solution were given. The patient rallied well from the operation and made an excellent recovery. The hearing distance on the left side is at the present time considerably impaired, although the incisions made in the drumhead have entirely healed.

Case II. Acute Purulent Otitis Media, followed by Mastoid Disease and Thrombosis of the Sigmoid Sinus; Operation; Recovery.—Charles S., seven years of age, was admitted to the infirmary January 28, 1899. Previous history: He had measles several years ago and scarlatina two years ago. Ten days ago he had an attack of influenza, and five days later the left ear began to pain and to discharge. He came to the clinic to-day for the first time with marked symptoms of mastoid disease, as shown by pain on pressure over the mastoid process. The drumhead had but a small perforation, so that a free incision was made and the Leiter coil applied. The ear was ordered irrigated every two hours with a mild bichloride solution, and the patient was given small doses of calomel.

January 29th.—General condition of patient improved, although pulse is weak, varying from 90 to 140. Temperature, 101.5° F.

31st.—The temperature yesterday rose to 103.6°, but to-day it has been lower, until this afternoon, when it began to climb up again. As there was considerable mastoid tenderness, an operation was decided upon. Under ether, the usual incision behind the auricle was made, extending from the extreme tip to a point half an inch above the attachment of the pinna. The periosteum was loosened from the bone, and an opening made in the mastoid process down to the antrum and tympanic cavity. The entire contents of the mastoid, consisting of softened bone and granulation tissue, were removed, but the sigmoid sinus was not exposed. The wound was dressed in the usual way.

February 1st.—Patient's condition worse. The temperature rose gradually to 105.8° F., pulse 146; child was dull and listless, and complained of pain about the wound. Thrombosis of the sigmoid sinus was diagnosed and an operation suggested, but the parents would not consent until the following day.

2d. Operation.—The incision made for the mastoid operation was continued upward for an inch, and another incision was made backward from about the middle of the mastoid wound so as to give space enough to uncover the sigmoid sinus. The latter was exposed from near the bulb upward for an inch and a half. Considerable softened bone was found, especially around the tip and bulbar region, with some pus. The sigmoid sinus was opened and free bleeding established from both ends. From the lower end toward the bulb the sinus wall was scraped with a curette and a parietal thrombus was removed. During this operation the patient's condition required constant watching, as the pulse became weak. Hypoderms of strychnine and whisky were given and oxygen gas was administered. The normal saline solution was also injected into the median ephalic vein of the right arm.

3d.—The patient had a good night and his general condition was much improved. The temperature did not go above 102.6°.

5th.—Temperature normal at 9 A.M., but it gradually rose to 102.4° at midnight.

10th.—The temperature was practically normal after February 7th, and the patient made an excellent recovery.

Case III. Acute Purulent Otitis Media, followed by Mastoid Disease and Thrombosis of the Sigmoid Sinus; Operation; Recovery.—Dora C., a Russian, aged nine years, admitted to the New York Eye and Ear Infirmary December 13, 1898. She gave no history of any previous illness. Eight days ago the child first had pain in the right ear, which was very severe, and for two nights she had been unable to sleep. Yesterday her mother first noticed a swelling in the post-auricular fold and in the neck just below the lobe. No discharge had been observed from the canal.

An examination of the ear showed a decided bulging of the drumhead, with redness and a drooping of the soft parts of the posterior superior wall of the canal. The tissues over the mastoid process and in the neck below the lobe were swollen and oedematous.

Operation.—Under ether, the usual mastoid incision was made behind the auricle, and pus was evacuated from beneath the periosteum. Considerable pus escaped, after which an opening was found in the cortex leading to the antrum. This sinus was enlarged, and the entire contents of the mastoid process were removed down to the tip. The inner wall of the mastoid was found absent, so that the sigmoid sinus was disclosed and found covered with granulation tissue, which was carefully scraped away. The entire mastoid tip, and also the softened bone, were removed. The sinus seemed to be soft and pulsedate. The wound was irrigated with a bichloride solution (1:1000) and then packed with iodoform gauze and bandaged in the usual way.
December 16th.—The temperature has shown many variations since the operation. On December 14th it reached 105.4° F. (rectal). From 10 P.M., December 14th, the temperature came down gradually to 99.6° F. at 10 A.M., December 15th, only to rise again steadily until it reached 106.2° F. at 4 P.M. The patient had a slight chill on the following day, and an operation for sinus thrombosis was decided upon at once.

On December 16th ether was given. The dressings were removed and the sigmoid sinus was uncovered. More bone was cut away, so that the bleeding from the sinus could be controlled. The sinus was compressed from above and below, and an incision was then made in the sinus wall between these two points. A large thrombus was removed with curettes and the blood current freely established above. At the lower end, toward the bulb, the blood flowed but slowly even after a curette was passed downward toward the bulb as far it could go. Although the thrombus had begun to break down and a drop of pus was found at its lowest extremity, it seemed better to me not to prolong the operation by ligating the internal jugular vein. After incising the sinus, it was plugged with iodoform-gauze tampons and the usual dressings were applied.

17th.—After the operation the temperature gradually fell to 100° F., but rose steadily again to 103.4° F. On the 18th the temperature fell to normal. On the 19th the temperature reached 102° F., but after this it was practically normal. From this time on the patient steadily improved, and on December 27th she left the hospital, but was to return to the out-patient department to have the wound dressed.

A study of the temperature charts of these three patients shows a decided rise and fall in the temperature, which is quite characteristic of sinus thrombosis.

In two of these cases there was a chill of moderate intensity followed by a rise of temperature. In one case the temperature rose to 105.3° F., in the second to 105.8° F., and in the third to 106.3° F.

Intestinal catarrh and pneumonia, either one of which is likely to occur in a child suffering from acute purulent otitis media following the influenza, may give rise to considerable fever, and thus occasion much difficulty in making a diagnosis of thrombosis.

If the mastoid cells have been thoroughly removed with all diseased tissue and the patient suddenly has a chill (in some cases so slight that it is likely to be overlooked), followed by a rise of temperature to 104° to 106° F., and other complications can be excluded, the diagnosis can almost certainly be made of sinus thrombosis, especially if there is tenderness along the neck over the internal jugular vein and there is a more or less edematous condition of the tissues below and behind the mastoid tip, and extending over the point in the skull where the mastoid vein enters.

The practice of giving some remedy, such as antipyrine or phenacetine, to reduce the temperature in a patient suffering from suppurative otitis media or mastoid disease, should always be condemned, as it is of special importance to make a diagnosis of sinus thrombosis at as early a stage as possible if an operation is to be performed. If the temperature is due to sinus thrombosis, such remedies, if used, are valueless, and only mask the symptoms.

Calomel should be given in one-tenth-of-a-grain tablets every hour until a cathartic action is produced, and is a remedy that should be administered in the early stage.

Pain is not a prominent symptom, and frequently is but little complained of, although in some instances it may be excruciating and radiate over the side of the head. As the mastoid cells are usually affected at the same time, there is apt to be considerable pain on pressure over different portions of the mastoid, especially in the neighborhood of the antrum and tip.

If the thrombus invades the cavernous sinus and the ophthalmic vein has become engorged, there may be a certain amount of edema of the eyelids on the corresponding side.

A symptom that is quite frequently noted in the early stage is the anxious and pallid appearance of the patient, who has beads of perspiration standing out on the face and forehead.

In all three cases reported the patients seemed dull and inclined to sleep, and the pulse of each patient was rapid, varying from 110 to 150. Other symptoms of sinus thrombosis are enlargement of both superficial and deep cervical glands, but this is not constant; over-distention of the mastoid vein, and tenderness on pressure along the course of the internal jugular vein, although this is usually observed in a later stage. Neuroretinitis is noticed in some cases, more especially in the later stages, but is by no means a constant symptom.

Still other symptoms are nausea, vomiting, vertigo, and constipation. In the later stage, when the thrombus has broken down and septic poisoning has occurred, there may be rigors, sweating, diarrhoea, septic pneumonia, gangrene of the lung, leptomeningitis, tonic and clonic contractions of the face, neck, and upper extremities, or paresis, strabismus, retraction of the head and neck, delirium, and coma.

I believe that much desirable information can be gained by making a bacteriological examination of the secretion from the external meatus in all cases of purulent otitis media. During the past winter such examinations have been undertaken by Dr. George Sloan Dixon, assistant pathologist of the New York Eye and Ear Infirmary, in many of my cases; and in one case in particular, of acute purulent otitis media, in which a few streptococci were found in the pus from the external auditory canal mixed with other micro-organisms, it was interesting to note that in the pus taken from the mastoid cells the streptococci were found in much greater number, while in the broken-down clot removed from the sigmoid sinus of the same patient the streptococci alone were found.

In a paper read before the American Otological Society in July, 1898, I made the following remarks, which
I desire at this time to emphasize: "Much can be learned from cultures made from the pus in cases similar to this one." (The case reported being one of double mastoid disease due to the presence of the pneumococcus.) They are always serious ones when the pneumococcus and streptococcus are found, and if one can be sure of their presence early in the disease, it may be stated in general terms that the case is likely to cause considerable anxiety." I believe that in those cases of undoubted infection by the pneumococcus or streptococcus, the inflammation starts simultaneously in the middle ear and attic, because the patient frequently complains at a very early stage of pain when pressure is made over the mastoid process. Percussion of the bone is not sufficient to detect mastoid disease. One should make firm pressure over each mastoid and thus compare the two sides. It is most important on this account, if pneumococci or streptococci have been found in the discharge from the ear, to make a large incision in the drumhead, extending from below the stapes to the lowest portion of the membrana tympani, in order to secure the best possible drainage.

The application of the Leiter coil is of but little avail in severe cases of mastoid inflammation due to the presence of micro-organisms.

In Case II the infection was undoubtedly due to the presence of the pneumococcus, while in Case III the streptococcus was found. I regret to say that a bacteriological examination of the pus was not made in Case I.

Thickening of the external wall of the sinus, frequently observed when the inner bony wall of the mastoid cells has been removed, is certainly a clear indication of the usual route by which the micro-organisms travel. The sigmoid sinus, being in close relation to the mastoid cells, is affected by direct contact with the diseased bone. The micro-organisms may, however, travel through fissures in the tympanic roof or antrum, or they may be carried into the sinus by means of small veins in the bone. When the sinus is first involved, the epithelium is swollen and desquamates, and coagulation occurs, the deposit of fibrin being limited to one side of the wall (parietal clot); or the whole circumference of the vessel may be involved (obstructing thrombus). The sigmoid sinus, a continuation of the lateral sinus and lying in the sigmoid groove, is joined by the inferior petrosal sinus to form the internal jugular vein. The sigmoid sinus, resting as it does against the inner bony wall of the mastoid cells, is of especial interest to the aurial surgeon, and is the sinus most frequently affected in mastoid disease. When disintegration of the thrombus takes place, the infective particles are carried first to the small vessels in the lungs and infections occur. In a similar manner the infection may involve the pleura, pericardium, brain, kidneys, or liver, or an abscess may form in the cerebrum or cerebellum. It will thus be seen that unless an operation for the removal of the thrombus is performed in the first stage, before the thrombus has begun to disintegrate, the result is almost certain to be fatal. The operation should be undertaken as soon as a diagnosis of thrombosis has been made. In Case I the operation was performed one week after the beginning of the earache. In Case II ten days elapsed between the first symptom of earache and the operation, while in Case III, eleven days after the beginning of the attack, a broken-down thrombus was removed. It is thus demonstrated that in eleven days' time after the first symptom of earache pus may be found in the sigmoid sinus.

The question of ligating the internal jugular vein is still one open to discussion, some otologists claiming that it is advisable in all cases to first ligate the vein. In Case III, although the thrombus removed from the sigmoid sinus had begun to disintegrate and contained a drop of pus at its lowest point, the internal jugular vein was not tied. Very little blood oozed from the direction of the bulb after the clot had been removed. It seemed to me advisable to wait for twenty-four hours before ligating the vein, with the hope that it would not be necessary to do this. Such proved to be the case. Unless we are quite confident that the thrombus has already extended to the internal jugular vein, it seems to me more prudent to give the patient the benefit of the doubt, for ligature of the internal jugular vein adds very much to the gravity of the operation.

On the other hand, if a thrombus has already formed in the internal jugular vein, or the sigmoid sinus contains purulent material, and especially if the patient shows symptoms of general infection, the internal jugular vein should be tied at once.

Although in many instances the sigmoid sinus has been incised accidentally or explored without apparent shock to the patient, still it must be remembered that the operation of removing an infective thrombus is a most serious one, and that the surgeon when operating should be prepared for all emergencies. After removing the thrombus, and especially if the internal jugular vein is tied, the patient frequently passes into a stage of collapse, and in addition to giving hypodermics of strychnine, whisky, etc., it is often imperative to inject into the median cephalic vein several ounces of the normal saline solution. The latter remedy is the most valuable means at one's command in such cases, and immediately after its use the pulse, which but a moment before could hardly be counted, becomes strong and much less rapid. When the patient is conscious and can retain the solution, it can be used per rectum.

It is not my purpose this evening, nor is there time, to discuss the various steps in the operation, the subject being an inexhaustible one. The points which I wish to draw your attention to are the following:

I. The propriety of giving antipyretics in all cases of suppurative otitis media.

II. The value of a bacteriological examination of the
secretion from the external auditory canal in all cases of suppurative otitis media.

III. The importance of operating at the earliest possible stage after a diagnosis of thrombosis has been made.

IV. The use of the normal saline solution during the operation for sinus thrombosis or immediately following it.

COMPARATIVE TEST OF MIXED-FAT EMULSION AND COD-LIVER OIL AT THE HOSPITAL FOR RUPTURED AND CRIPPLED, NEW YORK.

By W. J. MERSEREAU, M. D., House Surgeon.

In a special hospital as extensive as the one named above, there are always a large number of children who are anemic and poorly nourished. The reason for this is clear when it is considered that in the majority of instances the inmates are strumous, their diseases very exhausting, and usually of long standing. In addition to operative measures and various apparatus employed for their relief, particular attention is given in all cases to means for raising the general nutrition. Food and tonics, therefore, are of great importance in the treatment of such patients, and everything is used which gives reasonable promise of aid in this direction.

Attracted by the favorable reports on the treatment of pulmonary tuberculosis by the Russell emulsion of mixed fats, Dr. Virgil P. Gibney determined to test its value in cases presenting other tuberculous lesions at the Hospital for Ruptured and Crippled. It is not alleged in previous publications on this subject that the emulsion has any specific action upon tuberculous diseases, except as it improves nutrition by supplying in a readily absorbable form an element of food commonly lacking in sufficient amount and difficult of digestion in those suffering from such lesions.

Cod-liver oil having been in use at the hospital, it was decided, for purposes of comparison, to select a certain number of children and divide them into two groups, an emulsion group and an oil group, the diseases and general conditions in each to correspond as nearly as possible. This latter is perplexing, because no two patients are exactly alike, and may differ either in age, extent of disease, length of time ill, etc., the influence of which should necessarily be considered in estimating results, though the importance of these differences is difficult and often impossible to convey to the reader. It seemed wiser to the writer not to attempt to compare these variations, because of the danger of either exaggerating or slighting their importance; so that, except to mention the fact, nothing will be made of this feature. That the emulsion list should include nearly all of the very serious cases was partly due to the fact that it was the first arranged, but largely to the intention of the observers, as the emulsion was on trial. It is worthy of remark that it has been found from experiment that cod-liver oil, if pure, has food value, but is inferior to some other oils. This experiment was undertaken, therefore, with the purpose of determining the comparative nutritional value of the mixed-fat emulsion and cod-liver oil. They are here considered solely as foods.

The observations covered a period of thirteen weeks, from November 1, 1898, to February 1, 1899, and the children were examined and changes noted weekly in regard to the following particulars: Weight; local condition or suppurition; activity about ward; color; general condition. The importance of frequent and careful examinations of the blood during the experiment was not overlooked, but was necessarily omitted on account of the lack of proper laboratory facilities, due to the unfinished condition of the new hospital buildings.

In selecting the cases only two conditions were insisted upon: first, that constitutional treatment was required in addition to the surgical measures already in progress; second, that the child should remain in the hospital until the completion of the experiment.

The following table shows the number and kind of cases in each group:

<table>

Duration of disease for both groups, from three months to five years.

It was early learned that the emulsion was much more palatable when given in very hot water, and when so prepared there was no objection.

It was also found that, as many of the children were small and were wearing plaster jackets, it was important to keep the volume of the dose as low as possible, because of distention. With this in view, the first dose of two drachms was given in three ounces of water and increased to six drachms in the same amount. Later, in a number of the cases, the amount of water was reduced to two ounces and so taken perfectly well—in fact, more comfortably.

The cod-liver oil was given directly from a spoon or medicine glass in the pure state. The first dose was two drachms, increased to three drachms. Not a few of the usual complaints were heard from those taking it.

Weight. All of the children were weighed regularly on the same day of the week at about the same hour, unless some operative procedure prevented. As nearly all wore some sort of apparatus, or "plaster," subject to frequent change, the deductions, with the exception
of those given below, are of comparatively little value. No attempt was made to weigh them stripped, as few could have been handled without their braces, and the plaster, for obvious reasons, could not be removed weekly. The only reliable figures are those obtained from the first five weeks, very slight, if any, changes having been made in braces or plaster up to that time. From these we find that seventy-five per cent. of the emulsion group and fifty-nine per cent. of the oil group gained in weight. The aggregate gain of the emulsion cases was thirty pounds and a half; of the oil cases, fifteen pounds and a half. The losses amounted to six pounds and a half under the emulsion treatment and nine pounds and a half under the oil treatment.

Local Condition or Suppuration.—The number and condition of the sinuses, and the amount and character of the discharge from the same, were considered under this heading. Of the thirty-two children in the emulsion group, twenty were in a suppurring condition—that is, each had one or more pus-producing foel, discharging freely through sinuses. These all required dressing at least every third day, and some of them daily. Two have ceased discharging and the sinuses have either closed or are tending to do so.

Of the twenty-nine taking cod-liver oil, only six were suppurring, and one of these has ceased discharging, though the sinus has not yet closed. Six of the emulsion cases and one of the oil cases present a marked improvement, in that the discharge has decreased in amount, some sinuses have closed, and there is much less local pain and tenderness about the diseased joint. Toward the end of the last month there began to be a certain though not marked improvement in quite a number of children, not before noted. Seven of these belong to the emulsion group and one to the oil group.

Two in each group appear to have remained stationary throughout the period.

That in some of the serious cases the disease should progress, with an attending increase of the discharge and severity of the local symptoms, is not surprising to those familiar with tuberculous affections. This was the course which three of the emulsion group and one of the oil group followed. It should be added that in three of these four cases the patients had had a severe albuminuria from the beginning, probably indicating an amyloid or tuberculous kidney. Two had enlarged livers.

The history and course of two rather striking cases from the emulsion group may be briefly related here:

Case I.—A girl, five years of age; high dorsal Pott's disease; wearing the Knight spinal brace; had one discharging sinus over back, which, in spite of careful dressings and a number of curettages, has continued to discharge for about two years. At the sixth week the discharge began to decrease and became seropurulent in character. At present there is no discharge and the sinus is closing rapidly.

Case II.—A boy, ten years of age; right hip disease; very large abscess on outer thigh, opened and irrigated, followed by profuse discharge up to the eighth week, when it began to subside. By the tenth week the sinus was entirely closed. Since that time his hip has become somewhat more tender, but no abscess can be made out. He gained in weight, and at present has a fine color.

Activity.—Considerable difficulty was experienced in judging of their condition in this respect, due to the fact that about three fourths of the whole number were walking about. However, disregarding those, and simply considering those in bed, on cars, or in rolling chairs at the beginning of the experiment, we find that six cases from the emulsion list and one from the oil list show greater activity—that is, they are at present walking about. Two from each group remained stationary and four from each are less active than at the outset.

Color.—All the children, with the exception of six or eight, were pale, and many of them distinctly anemic in appearance. Several presented that peculiar "waxy" complexion seen with prolonged suppuration. No appreciable change in color was noted until about the seventh or eighth week, when a little color, more or less fugitive, began to appear in some of the faces. Soon, however, a more marked change was noticeable in the non-suppurative ones, and one or two who had some color to begin with now really had red cheeks, and a few of the anemic ones some color in the lips. By the tenth week improvement was apparent in most of the emulsion cases. Those in the oil cases showed improvement also, but it was less general and distinct.

Referring to notes, we find that seven from the emulsion group and two from the oil group showed a marked improvement. They could be said to have a "good color." Thirteen from the first and seven from the second certainly show a bit of color in place of their former sallow complexions. Twelve from the emulsion group and twenty from the oil group show no change whatever. Among the last-mentioned are the "waxy" ones spoken of above, one at least of which has cleared up favorably under the emulsion treatment.

General Condition.—At the outset only a very few of the patients could be said to be in good condition. Improvement in this respect followed closely after those noted above. This was seen in nearly all of the emulsion cases, manifested by greater activity, improved appetites, lessening of the discharge in suppurring cases, with consequent diminished local discomfort, gain in weight, a fullness of the face, and better color. The same occurred, to a certain extent, in the oil cases, but was later in making its appearance and was much less striking and general.

Referring to the notes again, we find that ten from the emulsion list and one from the oil list show a marked improvement. The cases which showed less, but at the same time a degree of improvement, stand twelve
to eleven in favor of the emulsion. Only three of the cases in the emulsion group show "no improvement" against seventeen in the oil list.

There were three cases from the first list in which the patients declined steadily during the whole time. They were desperate from the beginning, and among these and the following were all the cases in which the patients had albumin in the urine. Three deaths occurred from the same list: one from lobar pneumonia, one from septic meningitis, and one from tuberculous meningitis.

It may not be amiss to cite two cases at this point. In the first one the patient was thoroughly septic and in very bad condition:

Case I.—A girl, seven years of age, was "excised" for very extensive disease of the right hip. About twenty ounces of pus were evacuated at the time. Her condition was desperate indeed: emaciated; no color; no appetite; pulse rapid and feeble, temperature high. Was put on the emulsion treatment two weeks after the operation in about the above condition, with little hope that she would be able to continue it. However, the temperature dropped under frequent dressings, and soon the discharge lessened in amount. General improvement was apparent, which continued, and she is now walking about, wearing a brace, with almost no discharge from the operation wound. She is active, full in the face, and has a good color. Gain in weight, five pounds. As she wore the same apparatus, this record is reliable.

The following case was in the oil group up to the sixth week, when, for special reasons, the patient was transferred to the emulsion group. No apparent improvement had taken place up to that time:

Case II.—A girl, fourteen years of age, had longstanding left hip disease, with five sinuses in the thigh and groin, which had discharged for more than a year. General condition fair; in rolling chair most of the time; face a waxy white. She has gained in weight, is more active, and walks some of the time. Her face is clear white, with color in the lips. All but one of the sinuses have ceased discharging, and that one is improving steadily.

The results are tabulated in the following:

<table>
<thead>
<tr>
<th></th>
<th>Emulsion Group</th>

<td>22</td>
<td>3</td>
</tr>
</tbody>
</table>

To summarize briefly, we see that sixty-four per cent. of the patients in the emulsion cases were suppurating and several were in a desperate condition. Of these, seventy-five per cent. improved.

Of the oil cases, in which twenty per cent. of the patients only were suppurating and none were in a serious condition, fifty per cent. improved.

The weights, though continued through the whole experiment, were neither satisfactory nor conclusive, for reasons mentioned, with the exception of those for the first five weeks. These show the gains on the emulsion side to be nearly double and the losses about two thirds those on the side of the oil.

In color, sixty-five per cent. of the patients in the emulsion cases were improved, to be compared with thirty-one per cent. of those in the oil cases.

Under general improvement sixty-eight per cent. of those in the emulsion group, against forty-eight per cent. of those in the oil group, showed a gain, in spite of the much more serious condition of the former.

In conclusion, it may be said that there seems to be a certain better appearance, impossible to classify, about the patients in the emulsion group, which is in advance of that which may be deduced from the notes, though they show a striking gain over those in the oil group.

Note.—The hospital is indebted to Dr. John F. Russell for his kindness in seeing that emulsion was supplied for these experiments.

THE CHRISTIAN SCIENTISTS:
WHAT SHALL WE DO WITH THEM?*

By F. JULIAN CARROLL, M.D.,
SUMMERVILLE, S. C.

Mr. President and Fellow Members of the South Carolina Medical Association. Gentlemen: The general practitioner of this, the ending of the nineteenth century—and I believe the large majority of my audience is correctly classed as such—to be successful, must needs be a storehouse of much and diverse medical lore. This is an age preeminent of specialization. Indeed, if the specialists demand much more, the general practitioner will be of use only to direct the patient to the proper specialist. On the other hand, if we strive to keep up our prerogatives as general practitioners, we have to be more or less like the doctor who advertised himself as a "specialist on all the diseases of men, women, and children." To embrace such a comprehensive scope of knowledge takes more time than most of us have at our disposal. Thus it is that in our striving to keep up with medical progress we frequently allow to go unnoticed matters which, while they are, perhaps, strictly speaking, extraneous to medicine proper, are of vital interest to us as practitioners. Of these I should mention "Christian Science" as the most powerful and the most potent for evil. Possibly you think that this is stating the case rather strongly, but when I tell you that the

* Read before the South Carolina Medical Association at Harris Lithia Springs.
barenaked assertions of this money-seeking cult constitute
the religion of over two hundred thousand souls; that
this society is daily filling the country with its tracts
written by men and women of more or less ability; that
they publish a regular monthly journal, and that they
have their churches and meeting houses in almost every
city of any size in the United States; that their baneful
influence has permeated all walks of life, Harold Freder-
ic, a very prominent literary man, having died a victim
of this faith; when I tell you all this, perhaps you may
give the matter a little more thought.

That the medical profession, as a whole, is "slow
to anger and plenteous in mercy" is well known, and
that we are often negligent of our responsibilities and
interests, owing to our disinclination to appear in the
role of public accusers of charlatanism and professional
irregularities, is also a matter of common knowledge.
There is a limit, however, when patience ceases to be
a virtue, and in my opinion that limit has been reached,
so far as Christian Science goes. However, let us see
first what this Christian Science is.

We find that Mrs. Eddy has summed up the Chris-
tian Science religion in four remarkably misty propo-
sitions, as follows:

1. God is all.
2. God is good. God is mind.
3. God, spirit, being all, nothing is matter.
4. Life, good, God omnipotent deny death, evil, sin,
disease—disease, sin, evil, death deny, God omnipotent,
good Life.

Candor compels me to admit that this fourth propo-
sition looks auspiciously like a word puzzle from the
supplement of a Sunday newspaper; however, on closer
inspection, we find this lack of perspicuity is due in the
main part to a transposition of words from the middle of
the sentence—thus, deny death, evil, sin, disease—dis-
cease, sin, evil, death deny, etc.

In her third proposition Mrs. Eddy states, "God,
spirit, being all, nothing is matter." Now, it logically
follows, of course, that as "nothing is matter," matter
is nothing. Really, one is inclined to think that the
whole Christian Science edifice is built on—nothing!
In other words, according to Mrs. Eddy, the Bible
was in error when it said, "And the Lord made heaven and
earth, the sea, and all that in them is." There is no
earth nor is there a sea, and, as something can not
possibly exist in nothing, "all that in them is" is noth-
ing.

In view of our preconceived ideas of the reality and
indestructibility of matter, to be rudely informed that
"matter is nothing" rather knocks the props from under
us. "Of course," says Dr. Charles A. L. Reed, of Cin-
cinnati, "when one is confronted with the proposition
that 'matter is non-existent,' 'matter is nothing,' one
is very inclined to protest that one can see and feel
and taste matter; but our wily synthetic metaphysician
anticipates the criticism. We are told that the testimony
of our senses is always false; in other words, one knows
nothing of things by hearing, seeing, tasting, or smell-
ing them. . . . We are reminded of the primitive im-
pression that the sun seems moving from east to west
instead of the earth turning from west to east. An ex-
pression arising from the false testimony of the eyes,
but corrected by 'clearer views' of everlasting facts."

Dr. Reed continues pertinently and wittily: "Of course,
the observation is very conclusive, yet we might have
been a little more content in the conviction forced upon
us if we had been informed how these 'clearer views'
would have become possible had it not been for 'eyes,'
or how the science of astronomy could have become de-
veloped by an eyeless humanity."

Now, where does all this "nothingness" lead us to?
What is the object of Christian Science, and how are
these propositions put to practical uses? The special
application of Christian Science which concerns us as
physicians is that division of the "science" which re-
lates to the cure of disease, remembering, of course, all
the time that inasmuch as "sin, evil, death, disease" do
not exist, the "cure of disease" is simply a figure of
speech. Still, as the Scientists themselves have not in-
vented any words to supply the place of these obsolete
terms, we must use them to make ourselves understood.
How these "healers" accomplish their cures, and why
they do it, is illustrated by the following ingenious nar-
rative from the pen of the Rev. Jesse L. Fonda.* Un-
der the caption of Unconscious Healing he relates the
following among his other cures:

"The next case is in the same line, but not so pro-
nounced. It is of a man, a former parishioner, who had
poor health with financial troubles, and it was thought
that he was fast passing into softening of the brain.
It showed itself in violent paroxysms of temper and
anger." (At this point, were one inclined to criticise,
one might ask the Rev. Mr. Fonda exactly what distinc-
tion there was between "temper" and "anger," and
some of the more exact of us might be tempted to inti-
mate to the reverend gentleman that his history of cer-
bral softening might be a trifle more full without any in-
jury to its clearness. But let us hear him out.) "He
would fly into a passion on the slightest provocation and
had often threatened the life of his wife, and was a
terror to his children. A friend had told his wife
what Science did for such cases" (parenthetically one
might remark the connection between the wife's knowl-
dge of "Science" and the husband's threat on her
life; truly, the provocation was great), "urged them
to try treatment, and wrote to us about them. Money
matters prevented." (I beg you will give Mr. Fonda
due credit for this frank statement: "Money matters
prevented." ) "But the last letter that the friend re-
ceived from them contained the news that the husband
had entirely changed in his actions toward his wife."

—possibly because she had given up Christian Science
—and family, and was just as kind and tender as one
could be.

This case is quite a striking example both of the
miraculous curative powers of “Christian Science” and
of the willingness of this cult to work “for a considera-
tion,” and their corresponding unwillingness to work
without that “consideration”—in short, of their com-
mmercialism.

As regards the cure, one need not necessarily be en-
dowed with an overwhelming degree of skepticism to
arrive at the conclusion that the Rev. Mr. Fonda had
nothing in the world to do with this cure.

One of the first principles of this religion is that if
one wants to be cured he must have faith in the healer,
and, so far as I can see, this man, who was so miracu-
lously cured, did not demonstrate the faith of a “grain
of mustard seed.” Indeed, he seemed to take no stock
in the business, and probably like a sensible man put
himself under the care of a good physician.

If Mr. Fonda really believed that by his prayers and
incantations he could have cured this patient, his bare-
faced assertion that “money matters prevented” is es-
pecially astounding, and should fill all honest people
with disgust.

Here are a band of people collected together in the
name of Christ, and this man, the Rev. Jesse L. Fonda,
one of their chosen leaders, one who, I should judge,
occupied a “high seat in the synagogue.” On the other
hand, we have a poor stricken creature, according to Mr.
Fonda, “threatened with softening of the brain.” What
happens? What would we naturally expect to happen
under such circumstances? Does this leader extend the
helping hand of the “Good Samaritan,” as any Chris-
tian should and any physician would? No. He passed
by on the other side! And why? Simply and solely
because “money matters prevented.” There is no ex-
cuse, no evasion. It seems to be a clear business propo-
sition. “You pay your money and get your Divine
healing”—in short, “money up or shut up.” Is he
ashamed of himself? Well, hardly! Oh, no, he simply
claims “another cure,” folds his hands in meek content-
ment, and lays for a man with a fat purse and a bilious
complexion. Meanwhile the Scientists applaud this
righteous man!

These people base their powers of healing on the
miracles performed by Jesus Christ. In one of their
tracts they quote the miracle of the clay and the spittle:
“And when He had thus spoken He spat on the ground
and made clay of the spittle, and He anointed the eyes
of the blind man with the clay.” The tract then goes
on to say that the man was directed to go to the pool
of Siloam and wash this material remedy from his eyes;
which to this astute writer of the tract was an indica-
tion of our Lord’s contempt for material remedies.
Now Christ never did anything without a reason, and if
using material remedies signifies contempt for material
remedies, then dying in battle for the United States
shows undying admiration for Spain. In short, to my
mind the lesson is clear that while our Lord did not
himself have need of any material remedies, He did not
want to cast them into disrepute, and simply used this
one to demonstrate that fact. However, as clay does not
exist, and as spittle is nothing, it is begging an issue
for the Christian Scientists to argue about such mate-
rial things. In fact, in view of the non-existence of ma-
terial in general, medicines are imaginary and should
do no harm if they do no good; so our Christian Science
brothers are giving themselves needless trouble in dis-
paraging the use of drugs.

But let us go further, and read of more cures. On
page 508, Christian Science Journal, we find a narra-
tive of thrilling interest from Mrs. Corrine Bishop, of
Walla Walla, Washington. Right here, while disclaim-
ing any intention to pun, I am going to christen Mrs.
Bishop’s tale “Walla Walla Wash.” After hearing
her story I think you will agree that it is an appro-
priate title. It is as follows: “I was preparing to
scrub my kitchen floor, and had a large tub half full of
boiling water. My little boy, three years old, had a spool
of thread and began to unwind it, walking backward
and pulling the end of the thread. Over he went into the
tub, with his body under water except his face and the
forearms, with which he was holding on to the tub.
The other children began to cry and say, O, mamma, Earl
will be burned! I said, No, Earl is God’s child and can
not be burned! They stopped crying immediately and I
began to quiet their own fears.

“I took him out of the water as soon as possible,
removed his clothes, and put on his nightgown, without
examining to see if there were any effects from the
burns. He asked me to sing ‘Shepherd, show me how
to go,’ of which he is very fond. When I had finished
singing the hymn he looked up, smiled, and then fell
quietly asleep. When he awoke the next morning he
was free from pain! . . .

The foregoing recital is certainly very interesting,
nay, even extremely valuable. Think of the inestimable
boon this knowledge conveys to the poor hard-worked
mothers of the large family of the unwashed! In future
all they will need is a tub of boiling water, a spool of
thread, and the inevitable dirty urchin. The child
walks backward, unwinds the thread, and the tub and
boiling water do the rest! When we conceive that
the young one has boiled long enough to be clean—
vey, even surgically clean!—we take him, or her, out,
repeat the formula prescribed by the “Christian Sci-
entist” sister of Walla Walla, and put him or her
to bed and to sleep. One can not help confessing,
however, a feeling of intense regret that the angelic
“Earl,” who admired “Shepherd, show me how to go”
with such intense and pathetic love, when he took his
hot-water bath, should have neglected to include his
face and forearms in the boiling process, as some timid
mothers may entertain a doubt as to the perfect safety of completely submerging the dirty urchins in need of a bath. Such uncalled-for timidity will, of course, necessitate some additional labor in cleansing the members not included in the plunge, which is, to say the least, greatly to be deplored.

To us as surgeons this thrilling narrative can not fail to appeal. It has long been a question of much import as to the best method of rendering the hands perfectly sterile—in fact, there have been grave doubts expressed as to the possibility of such sterilization. Now, however, everything is simple, premising, of course, the impossibility of our microbial enemies adopting the Christian-Science religion themselves, and thus becoming unboilable. The “boiled hand” in surgery, so often spoken of in derision, will soon be an accomplished fact. But let us not grow too sanguine, for, as the following somewhat disappointing history shows, the best of plans sometimes go awry.

It really does seem a pity, though, after thinking of the glorious possibilities which Mrs. Bishop’s novel experience unfolds to our imaginations, to have our glowing and glowing enthusiasm roughly dispelled by being brought face to face with an apparently authentic ease of failure in our methods (presuming, of course, we have adopted the boiling process as our own). The New York Medical Journal for January 7, 1899, editorially remarks: “According to the New York Times for December 28th, a woman was so badly burned at Omaha on December 24th, by an explosion of boiling turpentine, that she died on the 27th from the effects of her injuries. The family, being ‘Christian Scientists,’ refused all medical assistance.” Now, we are not told that the woman suffered at all, and in the absence of any positive proof we must assume that she did not. However, she certainly did make a most unfortunate mistake in dying. Doubtless the operation was a perfect success and all that, but the patient didn’t live long enough to appreciate the benefits of it.

Now, whether boiling turpentine is less compatible with the integrity of the human epidermis and soft parts than boiling water, or the Omaha band of Christian Scientists did not possess the same fireproof coverings as the Walla Walla assortment, we are, of course, unprepared to say, but the fact remains that we would have been very much better satisfied had the Omaha lady shown the necessary resistance to heat. In passing, I should incidentally remark that in my humble opinion an extraordinary capacity for withstanding the effects of intense heat would seem to be quite a valuable addition to the Christian Science armamentarium, as they will in all probability need it—and need it like the Texan sometimes needs his pistol: mighty bad!—sooner or later, here or herafter, most likely the latter.

To imagine, however, that the “Christian Scientists” confine their attention to boiling children is to do them an injustice, for, though they are continually getting themselves and others “into hot water,” they are doing other things, as the following goes to prove: “A gentleman met with an accident which resulted in his being left with one leg shorter than the other. Medical science failed to put him to rights, and in despair he determined to try Christian Science. He was introduced to a healer who was said to have had miraculous success with similar cases. Unfortunately, the lady . . . was only able to see him once. She, however, commenced the treatment and departed . . . promising to continue the course in absentia . . . . The log began to grow. It continued to grow. It got as long as the other, but showed no disposition to stop growing at that point. The owner became alarmed. He made inquiries after the absent ‘healer,’ but failed to find her. His leg kept on growing, and in despair he advertised in the newspapers in the hope of stopping the absent treatment, but without success. His leg is now three inches longer than the other, and is still growing.”

The reflection which naturally occurs to one after a perusal of the foregoing is what a remarkable success this woman was at “pulling a fellow’s leg.” In fact, I believe the whole set make a specialty of pulling the public’s leg!

Now, to continue in a vein more serious, let us hear what Mrs. Eddy can do. She says: “I healed consumption in its last stages, the lungs being mostly consumed.” “I healed carious bones that could be deputed with the finger.” “I have healed at one visit a cancer that had so eaten the flesh of the neck as to expose the jugular vein, so that it stood out like a cord.” In reply to these Munchausen-like assertions Dr. Reed challenges all her statements and offers to place at her disposal cases of all the diseases mentioned, these cases to be under her absolute management. As yet we have heard nothing of her accepting Dr. Reed’s challenge, and are forced to assume that Mrs. Eddy is an unscrupulous and willful liar.

That such assertions as Mrs. Eddy’s should be taken seriously by over two hundred thousand persons is rather astounding. Still, they will give you dead loads of Biblical authority for their religion, and, as one of their writers, Eugene Hatcher, says, in the Arena for May, 1896: “There are scores of passages which support gospel healing, but not one against it.” This may be so. I am not prepared to say it is not so. Still, if we are going to regulate our everyday life by the miracles which the Bible speaks of, we’ve a job ahead of us. By that token Christian Scientists should never take ship to go anywhere. They should reasonably be expected to walk on the water. “Five loaves and a few small fishes” should feed their multitudes. They should never need for wine—they could always turn water into that! But why multiply the possibilities of this glorious religion? Two hundred thousand souls believe in it, and still, Mrs. Eddy to the contrary notwithstanding, people are dying, sin is being committed, many are falling sick, and mat-
ter still seems matter to most of us. "Dust to dust, ashes to ashes," still comes to us with appalling vividness, and the world still seems to turn in the old-time way.

Do the Scientists ever accomplish a cure? I should answer decidedly in the affirmative. To one who has seen the almost miraculous improvement in a patient on seeing his family physician, even before medicine is given, or experienced good results from bread pills or hypodermics of plain warm water—and most of us have seen all these—the value and potency of "suggestion" can not but appeal in certain cases. Few, if any, doubt the influence of hypnotic suggestion in nervous diseases and in dealing with hypochondrias.

I remember vividly a case of mine which simulated paralysis. The patient, a young girl, had been unable to move from her chair for months, and the case puzzled me considerably. I finally suspected hysteria and invited Dr. W. H. Prioleau, then of Summerville, to see the case with me. After giving the girl a very careful examination, we determined on a diagnosis of hysteria, and commenced a treatment of rather rigorous "suggestion." She soon got well, and has ever since been working out as a servant girl. This case would have been a fruitful one for a Christian-Science "healer" to work upon. Now, all of us could multiply similar cases where the successful treatment was mental rather than physical.

Unfortunately, however, the Scientists do not confine their pretensions to the treatment of fancied ailments: they claim to cure, and do attempt the cure of, such cases as diphtheria, phthisis, cancer, fractures, necrosed bones, etc., thus proving a serious menace to the safety of our commonwealth. And here it is that we, as physicians should act, and act vigorously.

What shall we do with them? We are told that one of these "healers," Harriet O. Evans by name, treated Thomas McDowell for typhoid fever by the usual Christian-Science method, with the result that McDowell now imagines he is dead. This seemed also to be the idea of Dr. Charles A. L. Reed, of the State board, for he succeeded in having the Evans woman convicted of practising without a license. Of course she appealed, but Dr. Reed's commendable zeal answers to a certain extent our question. Personally, however, I believe that all such persons should be criminally prosecuted for every case that dies under their treatment. I think if it were possible to pass a law to the effect that whenever a "Scientist" lost a patient we should hang the "Scientist," they would begin to think a little more seriously of the reality of "disease and death." The imagination would grow into conviction that a rope around one's neck was a very material and an intense reality.

In concluding, gentlemen, let me beg of you severally and individually to think of this matter seriously, remembering all the while that in matters medical the general public is not a discriminating public; that the masses as well as the classes are apt to be carried away by fads, and that it is our duty as family physicians to point out the absurdity of this unscientific and un-Christian eraze. Remember, also, that we are contending against a class of people who have gone over their grounds thoroughly, and, though their premises are false, their deductions are in the main logical; therefore we must use our wits in defeating them. Though assured that truth, reason, and honesty will finally prevail, let us hasten this culmination and the downfall of this iniquitous sect by something more than a passive disapproval.

EXCISION OF THE RIGHT SUPERIOR CERVICAL GANGLION OF THE SYMPATHETIC FOR GLAUCOMA,

WITH REPORT OF CASE AND REVIEW OF LITERATURE OF THE SURGERY OF THE CERVICAL GANGLIA.*

By JAMES MOORES BALL, M. D.,
ST. LOUIS.
PROFESSOR OF OPHTHALMOLOGY IN THE ST. LOUIS COLLEGE OF PHYSICIANS AND SURGEONS;
EDWIN C. RENAUD, M. D.,
ST. LOUIS.
ASSISTANT IN OPHTHALMOLOGY IN THE ST. LOUIS COLLEGE OF PHYSICIANS AND SURGEONS;
FORMERLY ASSISTANT TO THE EYE, EAR, NOSE, AND THROAT HOSPITAL, NEW ORLEANS;
AND
WILLARD BARTLETT, A. M., M. D.,
ST. LOUIS.

We desire to make this preliminary report of what we believe to be the first operation done in America for excision of the superior cervical sympathetic ganglion in glaucoma. For the sake of priority this report is submitted a few weeks after the operation:

Mrs. B. S., aged fifty-six years, was brought to our clinic May 10, 1899. Patient is deaf and dumb. Has had pain in and around right eye for two months. Vision in this eye is reduced to light perception; tension is +3. Pupil is widely dilated. Anterior chamber is shallow; cornea cloudy and slightly anesthetised. Media slightly cloudy, still allowing fundus to be seen. Episcleral vessels enlarged. Circumcorneal injection present. Optic nerve cupped. Diagnosis of chronic irritable glaucoma was made. Left eye presents immature cataract. Vision in left eye is 2/2.

Knowing the flattering results obtained by Jonnesco and others, by excision of the superior cervical ganglion in absolute glaucoma, we explained the operation to our patient through an interpreter, and obtained permission to operate. On May 15, 1899, the patient was anaesthetized, chloroform being employed. An incision four inches in length was made on the right side downward from the mastoid process, extending along the posterior border of the sterno-cleido-mastoïd muscle. The external jugular vein was cut and tied. The sterno-cleido-mastoïd was then separated from the trapezius muscle and the spinal accessory nerve was cut. A deep dissection was then made, exposing the carotid sheath. This was opened to enable us to locate the

* Read before the St. Louis Academy of Medical and Surgical Sciences, May 23, 1899.
pneumogastric nerve beyond question. The carotid, internal jugular, and pneumogastric nerve were then pulled forward, enabling us to see the rectus capitis anticus major muscle, on which the superior cervical ganglion rests. Tearing through the fascia, the ganglion was found and stripped. The ganglion was then cut high up with curved scissors and all its branches severed. About one inch of the trunk of the sympathetic below the ganglion was removed. There was no change in the pulse or respiration. The wound was closed with interrupted sutures and the neck placed in a plaster cast. Time required for operation was fifteen minutes. Immediately after the operation it was noticed that the right eye was suffused with tears, the right conjunctiva much injected, and the right nostril was moist. The intraocular tension was +2. Patient slept well all night, being free from pain for the first time in over two months. Temperature at 7.30 p. m. was 99.2°; pulse, 80. The patient's temperature has not at any time exceeded 99.8°, nor has her pulse exceeded 90. Tension has steadily decreased to +1.

On May 16th slight ptosis was noticed on the right side. This symptom is yet present.

On May 19th the circumcorneal injection was much less; the conjunctival hyperaemia and lacrymation were still present, while the ptosis was slightly increased, and tension was +1.

The immediate relief of pain in this case following the operation leads us to conclude that in absolute glaucoma excision of the superior cervical ganglion is justifiable, even though no other beneficial result is obtained. This operation is much preferable to enucleation.

The flattering reports which have been published in foreign medical literature by Jonnesco and others regarding the value of excision of the superior and middle cervical ganglia in exophthalmic goitre would lead us to operate on such cases at the earliest opportunity, provided ordinary medicinal treatment has failed.

In regard to glaucoma without complete loss of vision, we shall certainly employ this operation at the earliest possible date.

In conclusion, we desire to thank Dr. H. L. Nietert, superintendent of the St. Louis City Hospital, for privileges in the deadhouse. The operation was witnessed by Dr. J. C. Murphy, Dr. Fisher, Dr. Emory Lanphear, Dr. C. Heidemann, and Dr. O. F. Ball, of St. Louis, and Dr. Davis, of Independence, Kansas.

**Literature.**

The surgery of the cervical sympathetic system may be said to have had its initiative with Alexander, of Edinburgh, who resected the superior ganglion on both sides and described the operation in 1889.

Jacksh made it known in 1893 that he had resected the vertebral plexus and cut the cord connecting the middle and inferior cervical ganglia.

The third man to enter this field was Kümmel, who excised the superior ganglion on one side only.

In 1893 Bojadnik reported a bilateral resection of the middle ganglion.

Chipault, in his *Chirurgie opératoire du système nerveux*, of 1895, writes of the cervical sympathetic system as having been operated upon twenty-eight times.

Bilateral section of the sympathetic cord above and below the middle ganglion was made by Jaboulay in 1896.

All the above-cited operations were undertaken for the relief of epilepsy.

With one exception, the first surgical procedure of this kind in a case of exophthalmic goitre was that of Jonnesco, who resected the superior and middle ganglia on both sides in August, 1896, simple section of the sympathetic having been performed by Jaboulay earlier in 1896.

Jonnesco was the first, in 1896, to do a bilateral resection of all three cervical ganglia, though it is claimed by the Polish surgeon, v. Baracz, that he proposed the same in 1893.

To Professor Jonnesco, furthermore, belongs the credit of having first excised the superior ganglion for glaucoma in September, 1897.

Terrier, Guillemin, and Malherbo, in their *Chirurgie du cou*, of 1898, were among the first to give surgery of the sympathetic a place in a textbook.

As to the extent of the operation in the three diseases—epilepsy, exophthalmic goitre, and glaucoma: In epilepsy all three ganglia must be excised, because the carotid plexus is formed by branches which leave the superior ganglion and the vertebral plexus by branches which have their origin in the inferior one. It is clear that the entire intracranial vasomotor arrangement must be changed if we agree with Professor Jonnesco that the operation achieves its result in the following way: By transforming a permanent cerebral anaemia into a permanent hyperaemia, thus improving the nutrition of the cortical cells and flushing out toxic material contained therein. If the case is one of reflex epilepsy, the idea is to completely destroy all means of communication between the thoracic or abdominal viscera and the brain.

The similar procedure—namely, the removal of all three ganglia—is necessary in exophthalmic goitre. In proof of this, one has but to consider the anatomical relations. From the superior ganglion come the sympathetic nerves for the eye; from the inferior, the vasodilator, and in all probability the secretory nerves of the thyroid gland. The same ganglion furnishes the cardiac accelerator branches. It is then clear why the whole sympathetic chain in the neck must be removed if one expects to remedy eye, thyroid, or heart manifestations.

In glaucoma it is sufficient to remove the superior ganglion, as it supplies all the sympathetic nerves to the eye and intraorbital structures with the exception of those which are branches of the trigeminus. The operation here accomplishes its beneficial result in the following four ways:
In the first place, it inhibits vaso-constriction; hence the dilatation of the arteries, the lessened blood pressure, and the decrease of extravasation. Secondly, it inhibits secretion; hence the decrease of aqueous humor. Thirdly, it inhibits iris irritation; hence the contraction of the pupil, with opening of the canals in the iris angle and consequent easy outflow of the aqueous humor from the eyeball. In the fourth place, the circumbulbar unstriped muscles, which have been in a state of tonic contraction, are allowed to relax, and the normal venous circulation in the tunics of the eye is restored.

Glaucoma is not the result of a disease in the superior ganglion. Its removal, therefore, simply interrupts the transmission of pernicious impulses from the point of disease in the cerebrum or medulla where the sympathetic strands for the eye have their origin.

As to the results obtained in the surgery of the sympathetic for the three conditions—epilepsy, exophthalmic goitre, and glaucoma—we will state in full only those of Jonnesco, published in the Centralblatt für Chirurgie of February 11, 1899. Among those whose extensive experience has led to like results are Jaboulay, Abadie, Gerard-Marchant, Quenu, Chauffard, Reclus and Faure, Soulié, Corzez and Juvara, Gauthier and Combemale, Thivier and Boisson, Tuffier, Chipault, Nicard, Ottero, Donnath, and Beyer.

Jonnesco operated upon forty-five epileptics, with complete cure in fifty-five per cent. of cases, with an improvement in twenty-eight per cent., and no effect in fifteen per cent. The period of observation in these cases varied from two years to four months.

His experience with exophthalmic goitre was limited to ten cases. Six of these were absolutely cured and four greatly improved. He operated for glaucoma eight times; one case being of the acute variety, four of the chronic irritative form, and three of the simple chronic. His results with glaucoma were as follows:

1. Lessening of ocular tension, especially in four cases. 2. Vigorous contraction of the pupil. 3. Disappearance of periorbital pain and headache. 4. Disappearance of the attacks in irritative glaucoma. 5. Improvement of sight and increase in size of the field of vision in those cases where visual sharpness was still present and the atrophy of the papilla not complete.

All authorities who have had experience in the surgery of the cervical sympathetic system agree that it is one of the greatest advancements in the surgery of modern times.

Note.—Since the foregoing was written Dr. Ball, assisted by Dr. Renaud, has excised the left superior cervical ganglion in the case of Miss M. E., aged forty-three years, for chronic simple glaucoma. Vision in R.E. = 0; L.E. = light perception. Three days after operation vision in L.E. = ability to count fingers at three feet and a half. This patient sees with the nasal side of the retina (temporal field). Date of operation, June 16, 1899. This case will be reported in the near future.

—J. M. B.

Bibliography.

The Treatment of Cardiac Collapse.—The Indépendance médicale for June 7th attributes the following to Schilling:

R Camphor ................. 150 grains; Olive oil .................. 1,500 " M.

From thirty-two to a hundred and sixty minims to be injected hypodermically.

For Facial Neuralgia.—The Progrès médical for June 3d attributes the following to Bocquillon-Limousin:

R Butylchloral hydrate ...... 150 grains; Alcohol .................... 150 " Glycerin .................... 300 " Distilled water ................ 1,800 " M.

One or two teaspoonfuls daily.

The Treatment of Neuralgia.—The Riforma medica for May 30th ascribes to Eulenberg the following prescription:

R Ichthyol, Mercurial ointment, { of each . . . 52 ½ grains; Chloroform, Spirits of camphor, { of each . . . 300 " M.

For local application.

An Anaesthetic Arsenical Caustic.—The Journal des praticiens for May 13th gives Pouchet’s formula as follows:

R Arsenious acid, { each ................ 1 part; Orthoform, Alcohol, { each . . . 40 to 75 parts. Distilled water, M.

A Mixture for Pelvic Congestion in Women.—The Riforma medica for April 1st ascribes this formula to Roussel:

R Magnesium sulphate ............ 30 parts; Iron sulphate, } Manganese sulphate, { each . . . 8 " Dilute sulphuric acid, Distilled water AUD. 120 " M. S.: A tablespoonful in a glass of water before breakfast.
THE NEW GRADATION OF THE HARVARD CURRICULUM.

We learn from our highly esteemed contemporary the Boston Medical and Surgical Journal that with the coming academic year the Harvard Medical School is to enter upon an experiment in the line of an extension of a plan that has already been in operation to a certain extent in the Johns Hopkins University, "and, so far, with success," says our contemporary. It consists in a more thoroughgoing specialization, or "concentration," of the work to be done by the first-year and second-year students.

It seems that hitherto, since the adoption of the four years' course, the first half of the first year has been devoted to anatomy, physiology, physiological chemistry, and histology. On the new plan, the mornings in October, November, and December and the entire days in January will be given up to anatomy, and the allied branches of histology and embryology will occupy the afternoons of the first three months. During the second semester, which has heretofore been filled with anatomy, physiology, physiological chemistry, bacteriology, and embryology, physiology will be pursued in the mornings in February, March, and April and the entire days in May, with physiological chemistry in the afternoons of all but the last-mentioned month. "Full courses in pathology, clinical chemistry, second-year anatomy, and therapeutics, together with half-courses (without examinations) in auscultation and percussion, theory and practice, clinical medicine, bandaging, and surgical pathology, have heretofore comprised the second year's course." Hereafter the work of the first half of the second year will be in pathology during the mornings in October and November and the entire days in December. For the afternoons in October and November there will be a course in bacteriology. In January there will be optional courses in pathology, and during the last half of the second year a number of elementary subjects leading up to the clinical work of the third and fourth years will be pursued, such as auscultation (and percussion?), clinical chemistry, theory and practice, therapeutics, surgical pathology, bandaging, and clinical medicine.

These changes are represented as experimental. Who is to judge of the success of the experiment? It cannot be judged of in less than a generation, and the judgment must be based on the ultimate achievements of the men who are educated on the plan. Harvard men have thus far done well, and in our opinion there is much wisdom in letting well enough alone. The graded course itself is not yet beyond the stage of trial, and we question if it is wise to refine it to the degree indicated. So astute a teacher as the late Dr. Alfred L. Loomis declared himself in favor of clinical teaching during the whole course, and we are much inclined to agree with him. It is, to our way of thinking, absurd to argue that because a man has not come to his full strength in anatomy, physiology, etc., he can not study a case of disease or injury to his lasting advantage. Nevertheless, we shall look with interest on Harvard's experiment.

THE INDIANA STATE MEDICAL SOCIETY'S DEPARTMENT OF PATHOLOGY AND BACTERIOLOGY.

The exhibition of pathological and bacteriological specimens given in Columbus on the occasion of the recent meeting of the American Medical Association was a novel and most praiseworthy feature. It was given under the auspices of the Indiana State Medical Society, and was managed by a committee consisting of Dr. Frank B. Wynn, of Indianapolis (chairman), Dr. H. G. Gaylord, and Dr. A. W. Bitting, representing the society's Department of Pathology and Bacteriology. The collection had been shown at the society's meeting on June 2d, and had been considered so satisfactory that the meeting had made a generous appropriation to defray the expense of its display in Columbus, which was then and there decided upon. In all, there were between seven and eight hundred specimens shown, and to great advantage, it must be said, when we take into account the limitations under which the committee must have found themselves obliged to act. We understand that the committee not only supervised the exhibition, in itself no small labor, but actually collected the specimens, with the assistance of Dr. Roscoe Ritter, Dr. Conrad Marxer, Dr. Leland Westover, Dr. W. T. S. Dodds, and a number of medical students.

Two hundred and four of the specimens were photographs, two hundred were bacteriological, thirty-five were illustrative of comparative pathology—a matter on which the committee most properly laid stress in their report to the society—and the remainder exemplified embryology and the pathology of the bones and joints, the digestive system, the respiratory apparatus,
the circulatory system, the nervous system, the genito-urinary tract, and the organs of special sense, and the abnormalities of obstetrics and gynaecology. For a collection made and arranged within a comparatively brief period of time, as we understand it was, it showed most commendable activity and enthusiasm on the part of the committee and their associates, and no doubt it will prove the nucleus of a museum of which the Indiana State Medical Society will grow prouder and prouder year by year, for it will attest most strikingly the members' devotion to a work second to none in the task of perfecting our science and art. We congratulate the society and its committee on their creditable showing.

PELVIC CONTRACTION IN AMERICAN WOMEN.

It has generally been thought that pelvic contraction was quite rare in American women, but Dr. J. Whitridge Williams, associate professor of obstetrics in the Johns Hopkins University and obstetrician-in-chief to the Johns Hopkins Hospital, recently read before the Gynaecological and Obstetrical Society of Baltimore a paper, founded on the first thousand confinements in the hospital, which rather tends to lessen one's confidence in the freedom of our women from undersized pelvic straits. Dr. Williams's paper is published in the May number of the new journal called Obstetrics. There has, to be sure, been a lack of unanimity among our American obstetricians as regards this point. The late Dr. Lusk, for example, is cited by Dr. Williams as stating that pelvic contraction is very rare in native-born American women, while rickets and osteomalacia are absolutely unknown. Hirst, on the other hand, is cited as saying that the frequency of contracted pelvis has been decidedly underestimated.

Dr. Williams finds that there is a great diversity in the percentages of pelvic contraction in the statistics from various places in the same country. In Germany, for instance, they range from 7.9 per cent. in Basle to 24.3 in Dresden; in Austria, from 2.15 to 7.8 per cent.; and in the United States, from 1.13 per cent. in Boston to 11.45 per cent. in Baltimore, as reported by Dobbin. To some extent this diversity seems to be accounted for by variation in the meaning that the term pelvic contraction has for different observers; some of them count as instances of contracted pelvis all those in which any measurement is below the standard, while others set down only those in which the deformity is so pronounced as to impede labor. Dr. Williams puts down the Baltimore percentage as somewhat higher than that given by Dr. Dobbin, namely, 13.1 per cent., and this, he thinks, corresponds very closely with the average of frequency observed in Germany.

The relative frequency of pelvic contraction in Baltimore, according to Dr. Williams, is in great measure due to the presence of a large black population in that city; 469 of his thousand cases were in colored women. It is the equilibrater justo minor pelvis that predominates among black women, in whom it is more than five times as common as in white women. This, says Dr. Williams, is not what one would expect, in view of the fact that rickets is extremely common among the negroes of the South, and it is contrary to what is generally stated. Dr. Williams points out the interesting fact that there is a remarkable tendency in black women to a lack of correspondence between the external and the internal pelvic measurements. He properly accords to contractions indicated by external pelvimetry only the importance of hinting at the existence of corresponding contraction internally, but he implies that it rarely has even this significance in black women; he does not hesitate to declare that half of them would be found defective by external measurement, while in the great majority internal pelvimetry would reveal no contraction.

We do not gather from Dr. Williams's study that all his white patients were native American women. It would be strange if they were, for native white women do not resort largely to hospitals when they are about to be confined. All things considered, perhaps the general impression of the rarity of pelvic contraction among American-born women need not be further modified than to restrict it to the white race.

SHOP ASSISTANTS AND SEATS.

The Lancet for May 27th has an editorial on the "causes of female disease distinctly traceable to the practice of continually standing in shops." The Lancet says that the only argument with any semblance of legitimacy that has been advanced against providing shop assistants with seats is that sitting is conducive to idleness. It distinctly shows up the fallacy of that idea, and on the contrary enunciates the view that the very fact that the girl is not allowed to sit down is conducive to idleness of the worst kind—the idleness of pretending to do something when nothing really is being done. If the girls, it says, were allowed to sit in the intervals, they would be recuperating from fatigue and so be able to render better service. The Lancet has long done yeoman service in this cause for English shop girls. In 1880 it published a black list of large firms which refused to provide seats for their female employees, the effect of which was very marked. The Lancet now makes the following appeal: "To the true woman—the woman with feelings for her sisters, the woman of love and sympathy, the true woman in every sense of the word—we appeal for help in this matter. If such
women would abstain from purchasing at shops where they see that the employees are compelled to work from morning till night without permission to rest from their labors even when opportunity occurs, we should soon see the end of a practice which ruins the health and shortens the lives of many of our shop girls. To such women we feel that we shall not appeal in vain, especially when we remind them that the physical vigor of the future race depends even more upon the health and strength of woman than it does upon the health and strength of man." England is not the only place where this barbarous custom prevails of compelling shop girls to stand during their long, weary working hours, and we trust that something will be done here in this city of New York to secure for shop girls the right to rest in the intervals of their labor, thus preserving their own health and that of the future mothers of many a young American.

"THE SIGN OF THE FOOT" AND THE DREYFUS CASE.

Our readers are of course familiar with the fact that when a man is sitting with one leg thrown comfortably over the other, the foot that is hanging loose undergoes a little movement at each beat of the heart. While the charge against Captain Dreyfus was pending, the Marquis du Paty de Clam made a psychological study of the prisoner. Among other things, he suddenly asked Dreyfus a question calculated to arouse emotion in him if he was guilty. Dreyfus was in the posture mentioned, and the movements of his foot were suddenly intensified. The marquis urged this as a proof of the prisoner's guilt, and it really seems to have played a part in securing his conviction. Dr. A. Lautaud combated the marquis's inference at the time, and quite justifiably, we think, but we cannot agree with Dr. Lautaud when he says now, in a sarcastic article reflecting on du Paty de Clam (Journal de médecine de Paris, June 4th), that such movements of the foot, which he calls "instinctive," have nothing to do with the movements of the heart. The movement has been called "the sign of the foot," but Dr. Lautaud proposes to call it "du Paty's sign."

THE TREATMENT OF PULMONARY TUBERCULOSIS BY SUBCUTANEOUS INJECTIONS OF VASELINE.

M. H. Weber, of Saarbrucken (Presse médicale, May 31st), made a communication to the Berlin Congress for Tuberculosis in which he pointed out that various facts had called his attention to the phenomenon that a blood highly charged with carbonic acid seemed inimical to the growth of the tubercle bacillus. He referred to Bier's treatment, by means of venous hyperemia; the rarity of pulmonary tuberculosis in cardiac diseases accompanied by a pulmonary venous stasis; the frequency of the occurrence of tuberculosis in the apices, which were "insufficiently irrigated" (mal irrigués); and the frequency of tuberculosis in persons whose blood contained but little carbonic acid. Vaseline, a hydrocarbon which is oxidized in the system into water and carbonic acid, seemed to him a suitable agent for carrying out this treatment. He therefore treated thirty patients by injecting daily beneath the skin of the back ten cubic centimetres of vaseline. On occasion, he gave three injections in a day. Of these thirty cases he considered eighteen, for the most part in advanced stages, practically cured, inasmuch as for some months the patients had returned to their work and seemed to be in good health. Six others still under treatment were in a fair way to recovery; in four the cases were too recent to pass judgment upon; and two had succumbed to the phthisis. This is suggestive, and to some extent confirmatory, of Hildebrandt's views as to the modus operandi of abdominal section in peritoneal tuberculosis.

THE DANGER OF SEXUAL CONNECTION FOR SUBJECTS OF HEMOPTYSIS.

Moncorb (Médecine moderne, May 10th; Indépendance médicale for May 31st) calls special attention to the particular danger of copulation for phthisical patients subject to hemoptysis. Not only is sexual connection contrary to the necessity of conserving the vital forces, but it seems to have a special determining influence, according to this observer, on attacks of hemoptysis. Whenever the author meets with a case of sudden nocturnal hemoptysis of undetermined cause, he always bears this question in mind. It is not difficult to conceive that the exertion and vascular excitement occasioned by the act might determine hemoptysis in a patient predisposed thereto; and in any case, should such a thing occur at night, it affords a good opportunity for impressing upon the patient the necessity of abstinence from all sexual excitement.

THE OVARIAS IN RELATION TO SEX FORMATION.

We published in our last issue a note upon the Roulet of Pregnancy in reference to the theory of Dr. Nicolopoulos that the right ovary produced males and the left females. The Journal de médecine de Paris for May 28th publishes an observation by Winckel, of Munich, which is rather an awkward fact for Dr. Nicolopoulos's theory. Dr. Winckel at one time removed the left ovary of a woman, thirty-seven years of age, who had already had five daughters and four sons. After the removal of the left ovary she should, in accordance with Nicolopoulos's view, which appears to be only a practical application of Seligson's theory, have been capable of producing only boys; but of five subsequent pregnancies the result was three girls and two boys. This observation precludes the possibility of even an explanation based upon transposition of the viscera.

"SHADOWGRAPHS" OF MICROSCOPIC OBJECTS.

The illustrations given in connection with Dr. Hartigan's article, published in this issue, seem to show great nicety in the representation of minute details of structure, although they are considerably reduced in size from the author's original photographs. We may well imagine that the process he describes is likely to be used extensively for purposes of demonstration.

THE UNEXPLAINED ESCAPE OF AN OVARY.

It is rumored that an ovary with a cyst as large as a chestnut was recently found in a dissecting-room subject. We may fancy that the demonstrator of anatomy and his assistants are still wondering how it eluded the oophorectomists.
POEHL'S SPERMINE AS AN AID TO THE VISUAL POWER.

Whatever promises to revive the waning power of sight is certainly worthy of attention. At a recent meeting of the Ophthalmological Society of St. Petersburg (Presse médicale, May 20th) Dr. Yakovlev reported a gratifying degree of success (inversely proportionate to the loss of vision, but amounting to nothing in cases of total blindness) in the treatment of atrophy of the optic nerve by means of Poehl's spermine in Professor Belharminov's service. It was injected subcutaneously, and fifteen injections produced all the benefit that was to be obtained from the treatment. Analogous results had been achieved in chronic choroiditis and alcoholic amblyopia, but not in acute cases.

THE INDEX MEDICUS AND THE PARIS INSTITUT DE BIBLIOGRAPHIE.

With characteristic vehemence, Dr. Marcel Baudouin (Gazette médicale de Paris, June 10th), after properly recounting the excellence of the Index Medicus and announcing the suspension of its publication, declares that its discontinuance is a disaster to medicine and calls upon the Institut de bibliographie to take up the work without a week's loss of time. We trust that it will be resumed, but we can not see that the exigency is quite so sharp as Dr. Baudouin pictures it, especially as the new series of the Index-Catalogue is well under way and will doubtless be succeeded by still other series.

"BOSSISM" AND FIRST AID TO THE INJURED IN PARIS.

Our progressive colleague Dr. Marcel Baudouin, the editor-in-chief of the Gazette médicale de Paris, laments in the issue of that journal for May 27th the futility of his attempts to secure the establishment of an efficient system of rendering prompt aid to the injured. It is in vain, he says, that the municipal council has voted in favor of his project; the all-powerful A. J. Martin, grand master of inertia and malevolence, stands in the way of its enforcement. The occasion of Dr. Baudouin's plaint is the accident of a man's actually being hurt seriously in a duel and failing to receive prompt and effective medical aid.

THE PHYSICIAN AS A PIONEER IN CIVILIZATION.

In a well-conceived editorial article entitled The Medical Factor in Imperial Expansion, the Lancet for May 27th sets forth impressively the importance of the part played by two medical missionaries, Dr. David Livingstone and Dr. Stewart, in extending civilization in Africa by the power, not alone of religion, but also of "nature-study in its medical department." There can be no doubt of the truth of the Lancet's view that religion and medicine are powerful allies in reclaiming savage races, and it would not be strange if American counterparts of Livingstone and Stewart were soon to find themselves in the Philippine Islands.

DISPLACEMENT OF THE EYEBALL IN A GLASS-BLOWER.

The popular tradition that the eyeball can be "laid out on the check, scraped, and put back again" is almost justified by a case reported by Dr. Fritz Schanz, of Dresden (Beiträge zur Augenheilkunde, xxxiv; Deutsche Medicin-Zeitung, June 5th). It was that of a glassblower accustomed to blowing with his cheeks instead of with his chest. This in time led to distention of Stenson's duct to the size of the urethra, so that the parotid gland was blown up with the man's efforts. Moreover, the oro-nasal cavity came eventually to communicate with the orbit, so that when the man blew his nose enough air found its way into the orbit to cause the eyeball to protrude beyond the palpebral fissure. The optic nerve had suffered in consequence; at least the visual power had been reduced to less than half without any changes recognizable with the ophthalmoscope.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending June 24, 1889:

Yale University.—The annual address in medicine was delivered on Tuesday, June 27th, by Professor Charles S. Minot, of Harvard University.

The Buffalo Academy of Medicine.—At the last meeting of the Section in Obstetrics, on Tuesday, June 27th, Dr. William P. Spratling, of Craig Colony, Sonyea, N. Y., presented a paper entitled A Study of the Temperature Laws in Epilepsy, based on One Thousand Observations.

Changes of Address.—Dr. Harrison C. Allen, to No. 274 Fifty-first Street, Brooklyn; Dr. R. E. Coughlin, to No. 286 Forty-seventh Street, Brooklyn; Dr. Andrew F. Currier, to No. 113 East Fortieth Street, New York.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 17 to June 24, 1899:

Bath, Thomas W., Acting Assistant Surgeon, will proceed to Fort Leavenworth, Kansas, to accompany Troop F, Sixth Cavalry, to San Francisco, and then report to the commanding general, Department of California, for duty.
Borden, William C., Captain and Assistant Surgeon, is granted leave of absence for two months, to take effect on or about June 1st.
Boss, Rufus D., Acting Assistant Surgeon, will proceed to New York city for duty.
Combe, Frederick J., Major and Surgeon, United States Volunteers, is assigned to duty at the medical supply depot, Santiago, as officer in charge, relieving Geddings, E. V., Acting Assistant Surgeon, who will report at Santiago for duty.
Feller, Leigh A., First Lieutenant and Assistant Surgeon, will report to the commanding officer at the United States Military Hospital, No. 1, Havana, for duty.
Gardner, Edwin F., Major and Surgeon, is granted leave of absence for one month.
Gerard, Joseph B., Major and Surgeon, is granted leave of absence for one month on account of sickness, with permission to leave the limits of the department.
Gray, William W., Major and Surgeon, will proceed to Fort Logan, Colorado, to accompany the Twenty-fifth United States Infantry to Manila.
Hicks, John R., Acting Assistant Surgeon, will proceed to Fort Riley, Kansas, to accompany Light Battery C, Third Artillery, to San Francisco.
Raynor, Willis J., Acting Assistant Surgeon, will report to the commanding officer of the Twenty-fifth United States Infantry to accompany that regiment to Manila.
Summerville, W. B., Acting Assistant Surgeon, will proceed to Matanzas, Cuba, for duty.
Swift, Eugene L., Captain and Assistant Surgeon, is detailed as a member of the general court martial at Fort Slocum, New York.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Week ending June 24, 1899:

Atlee, L. W., Surgeon. Detached from the Boston and ordered to the Bennington.
Furlong, F. M., Assistant Surgeon. Detached from the Independence and ordered to the Solace temporarily, for passage to the Asiatic Station.
Hendon, C. G., Surgeon. Ordered home to await orders, on completion of temporary duty at the recruiting rendezvous at Chicago, Cleveland, etc.
Ward, B. R., Passed Assistant Surgeon. Detached from the Bennington and ordered to the Boston.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Week ending June 22, 1899:

Irwin, Fairfax, Surgeon. Granted leave of absence for three months from July 8, 1899, with permission to go beyond the sea.
Cafer, H. R., Surgeon. Detained as quarantine officer of the port of Havana, Cuba, under the provisions of Executive Order of January 17, 1899.
Banks, C. E., Surgeon. To proceed to New York for special temporary duty.
Weitenbaker, C. F., Passed Assistant Surgeon. To proceed to Danville, Virginia, for special temporary duty.
Smith, A. C., Passed Assistant Surgeon. Granted leave of absence for thirty days from July 15, or when relieved.
Stewart, W. J. S., Passed Assistant Surgeon. Granted leave of absence for fifty-two days from June 19, 1899.
COPER, L. E., Assistant Surgeon. To proceed to El Paso, Texas, as inspector.

SIBREE, H. C., Acting Assistant Surgeon. Granted leave of absence for ten days from June 21, 1899.

WAKFIELD, H. C., Acting Assistant Surgeon. Granted leave of absence for thirty days from June 15, 1899, on account of sickness.

GAIN, HENRY, Hospital Steward and Chemist. To proceed to New York on special temporary duty.

MASON, W. C., Acting Assistant Surgeon. Granted leave of absence for six days from June 26, 1899.

Promotion.

SLOUGH, CHARLES, Junior Hospital Steward. To be senior hospital steward.

Resignation.

STEWART, W. J. S., Passed Assistant Surgeon. Resignation as passed assistant surgeon accepted as tendered, by direction of the President, to take effect August 9, 1899.

Society Meetings for the Coming Week:

MONDAY, July 3d: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society, New York (private); Brooklyn Anatomical and Surgical Society; Corning, New York, Academy of Medicine; Utica, New York, Medical Library Association; St. Albans, Vermont, Medical Association; Providence, Rhode Island, Medical Association; Chicago Medical Society.

TUESDAY, July 4th: Elmira, New York, Academy of Medicine; Ogdenburgh, New York, Medical Association; Syracuse, New York, Academy of Medicine; Hudson, New Jersey, County Medical Society (Jersey City); Androscoggin, Maine, County Medical Association (Lewiston); Medical Society of the University of Maryland (Baltimore).

WEDNESDAY, July 5th: Medical Society of the County of Richmond, New York (New Brighton); Bridgeport, Connecticut, Medical Association.

THURSDAY, July 6th: Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, New York, Medical Society of City Hospital Alumni, of St. Louis; Atlanta Society of Medicine.

FRIDAY, July 7th: Clinical Society of the New York Post-graduate Medical School and Hospital.

SATURDAY, July 8th: Miller’s River, Massachusetts, Medical Society.

Letters to the Editor.

Coughing as a Remedy for Hiccough.

POTTS, Vt., June 20, 1899.

To the Editor of the New York Medical Journal:

Sir: Permit me, through the Journal, to call the attention of physicians and others to the relief afforded by gargling the throat in hiccough. I have had no very serious cases; but in every case where a gargoyle has been used it has been prompt and effective in its results. In most cases, once gargling has been sufficient. Cold, warm, and slightly medicated waters have been severally used, but the act of gargling seems to be the one thing needful. I should like to have this method of relief thoroughly tested.

Laura M. Plantz, M. D.

The Law in its Relations to Physicians

By Arthur N. Taylor, LL.B.

XXV.

Civil Malpractice, Including General Liability of Physician to Patient.

(Continued from vol. 12, no. 290)

Failure to Reduce Dislocation.—While in some cases, like the one above given, the question of the physician's liability for unskilfulness and negligence grows out of his failure to discover the extent of the injury sustained, it more frequently happens that the question of liability arises where the character and extent of the injury are discovered, but the fact of whether or not the
physician effected the relief attempted is disputed. Questions of this sort frequently arise in cases of dislocation in which the injury is treated with supposed success, but after weeks, or perhaps months, it is found that the bones are not in proper place. Upon the trial of this class of cases the testimony is almost always conflicting, that of the patient tending to show that the dislocation was never properly reduced, while that of the physician positively denies the failure to properly reduce the dislocation, and accounts for the bones subsequently being found to be dislocated by negligence of the patient or his failure to observe instructions, or other similar cause.

In the case of Rowe vs. Lent, the patient suffered a dislocation of the right shoulder. The family physician, after considerable effort and some difficulty, succeeded, as he claimed and still claims, in reducing the dislocation. The injury occurred in January, and the physician continued to attend the patient until July 24th following, when he claimed a cure had been effected. He frequently saw the patient, however, and examined the shoulder between this date and August 13th, when the patient left his home, going to the seashore to take sea baths. On about the 14th of August the patient was examined at a New York city hospital, and it was found that his shoulder was dislocated. The surgeon in charge made an attempt to reduce the dislocation, but was unsuccessful. The injury still continues and is conceded to be permanent. Upon the question of whether or not the dislocation had ever been properly reduced, there was some non-professional testimony introduced at the trial that the right shoulder did not look like the left; but some of the expert testimony tended to show that the difference in appearance might exist even if the dislocation had been properly reduced.

The case was submitted to the jury, who found for the plaintiff. The general term of the supreme court refused to disturb the verdict of the jury, and, after laying down the general rule that a physician must possess a reasonable degree of learning and skill, said: "The test, however, seems to be, whether in the case on trial the requisite skill, care, and diligence were employed, and not whether the practitioner is reputed to possess such skill. But the surgeon is not necessarily chargeable with want of the requisite skill, or negligence and want of care, simply because he does not succeed in accomplishing the desired result. Human skill can not relieve all infirmities, ills, or injuries to which mankind is subject, and the only test, therefore, that can be applied is whether in a given case the surgeon has exercised reasonable skill and attention in his treatment of the patient who has placed himself under his care, and whom the latter has undertaken to treat. As we have seen in this case, that the question was before the jury upon evidence somewhat conflicting, and the whole case was fully and fairly left to them by the charge of the trial judge given in an able and impartial manner, to which no exception was taken by the counsel for the defendant, and the jury upon this conflicting evidence found in favor of the plaintiff. While perhaps they might, upon this evidence, have found either for the plaintiff or defendant, there is sufficient evidence in support of their conclusion to uphold a verdict, and the court upon appeal can not say their verdict was either against the evidence or unsupported thereby." The foregoing quotation is made at this considerable length for the reason that it so clearly marks the policy of the courts and of the law in suits of this character.

An interesting suit, based upon the alleged failure of the physician to reduce a dislocation, is that of Carpenter vs. Blake, decided by the supreme court of New York in 1871. The patient was thrown from a horse and her elbow joint dislocated. The defendant was called to attend the injury and claims that he properly reduced the dislocation; the patient, on the other hand, claims that he did not succeed in restoring the bones to their places, or, if he did succeed in the original operation, that he failed to employ proper measures to keep them there, and upon this theory brought suit.

The evidence produced at the trial was voluminous and conflicting. The injury occurred on June 28th, and the defendant was called at once to attend the injury. The plaintiff testified that the physician simply drew the arm around his knee and placed it on a pillow at her side, bent at nearly a right angle; that she did not hear the characteristic "snap" caused by the bones falling into place, and that there was no relief from the pain.

The defendant testified that upon setting the joint he extended and rotated the arm and applied his hand to the joint, satisfying himself that the bones were in place: the plaintiff denied that he applied either of these tests. It is conceded that the defendant did not measure the arm to determine beyond peradventure that the bones were in proper position. The plaintiff and other witnesses testified that they observed a protrusion at the elbow joint the night of the injury, and compared it with the other elbow and inquired what it was. It appeared that the arm retained, when not controlled by splints, about the same position it was in after the first attempt to reduce the dislocation, and at no time could the plaintiff move it without producing severe pain. The defendant insisted that she must move it. When she attempted it, the pain was so great she had to call for help, and even then had to cease the attempt because of the suffering it caused. This was known to the defendant, and yet it did not seem to put him on inquiry whether he had not failed to properly set or treat the arm. The plaintiff was satisfied that the joint was never properly set, and so told the defendant; and, to ascertain whether or not her suspicions were correct, called other doctors. This was in the latter part of August, about two months after the injury was received. The defendant deserted the case at about this time. Other physicians were then called, and, after rendering the patient unconscious by the use of anaesthetics, reduced the dislocation. The bones, however, soon returned to their former position, and have remained there ever since. The jury upon this evidence found for the plaintiff, assessing the damages sustained at two thousand dollars.

**Failure to Apply Extension.**—In the case of Barns vs. Means the improper treatment complained of was the failure of the physician to properly extend the broken limb from which the patient was suffering, whereby the wound healed improperly. The evidence showed that the fracture of the larger bone was oblique, and near the upper part of the lower third of the limb; the fracture of the smaller bone was transverse, and was from two to three inches above the ankle joint. The defendants were called at once and dressed the injury within twenty or thirty minutes after the bones were

*Rowe vs. Lent, 42 N. Y. 8. R., 483.*

*Barns vs. Means, 82 Ill., 379.*
broken, but did not use extension or counter-extension. The excuse made by the defendants for not extending the limb and using counter-extension to hold it in place was that the extreme tenderness and swelling would not permit of their so doing, and they introduced evidence to show that some days after the fracture was adjusted they did attempt extension and counter-extension, but that the patient could not endure it. Upon the question of the condition of the limb at the time the injury was first adjusted there were several witnesses who were then present and who testified that no swelling had then occurred.

An expert testified before the jury that the shortening was caused by the lapping of the bones; that the first duty of the surgeon was to bring the bones to their proper position by extension and counter-extension, and if necessary he placed the patient under the influence of chloroform; and that if the patient would not allow a proper adjustment of the fracture he would abandon the case.

The trial judge, in instructing the jury upon the law applicable to the case, said: "That if you believe, from the evidence that, in the treatment of fractures of bones, regard should be had to the direction in which the break occurred; and if the jury believe, from the evidence, that the fracture of the bones of the plaintiff, which the defendants treated, required extension in order to secure the proper adjustment of the parts to each other, and that the defendants did not use any means to secure extension, but, by want of skill, or by negligence, suffered the broken fragments to be or become displaced, and that thereby the plaintiff has suffered and become permanently lame and disabled, as charged in the declaration, you should find the defendants guilty." Upon this instruction, which was held to be a correct statement of the law applicable to the case, the jury found for the plaintiff and assessed the damages at one thousand dollars.

The foregoing cases being thought sufficient to illustrate the application of the general rule of liability, a more critical examination will now be made as to the particular requirements of the rule.

Degree of Knowledge, Skill, and Care Required.—

The part of the general rule upon which the courts seem to have found the greatest difficulty in agreeing is that relating to the amount or degree of knowledge, skill, and care that the physician is obliged to possess and exercise to escape from liability for injurious results that may follow his treatment. To place the test as that degree exercised by the thoroughly educated members of the profession would be manifestly unjust to the great majority of the physicians and surgeons, while a test requiring only that skill exercised by the moderately educated members would be equally unjust to the public. Upon this reasoning the supreme court of Iowa placed the test as the average of the skill and diligence ordinarily exercised by the profession as a whole.* While this rule is probably a just one and about right in theory, it is doubted whether any practising physician knows what is the "average of the skill and diligence ordinarily exercised by the profession as a whole," and, as he is the proper judge of whether a given act will stand this test, the utility of the rule is doubted.

While the degree of care necessary to be bestowed in a particular case is governed in a great degree by the requirements of that case, a rule of law demanding that the degree of care and skill required shall be proportionate to the severity of the injury or disease treated would manifestly work a great hardship upon the profession. Such a rule was very wisely and justly rejected by the supreme court of Illinois.*

The location of the particular practitioner should also be taken into consideration in determining the amount of knowledge and science he shall possess and the degree of care and skill he shall exercise, because, for reasons heretofore referred to, the physician and surgeon practising in our large cities may be reasonably required to possess higher qualifications than those in small towns or rural districts. This indulgence should not, however, be allowed to the country practitioners to the extent of permitting them in each particular neighborhood or community to establish by their own professional standing the standard of requirement for that community; for, in the words of Justice Worden, "there might be but few practising in the given locality, all of whom might be quacks, ignorant pretenders to knowledge not possessed by them, and it would not do to say that because one possessed and exercised as much skill as the other he could not be chargeable with the want of reasonable skill." After due regard for all of these conditions, a number of our courts in well-considered decisions have determined the proper test to be that there shall be required of the physician and surgeon that amount of knowledge, skill, and experience, and the exercise of that degree of care and skill which physicians practising in similar localities ordinarily possess and exercise.†

Illustrations.—A case illustrating the application of the law very nicely is that of Small vs. Howard.‡ In this case the plaintiff, who had cut through the whole inside of the wrist to the bone, severing all the arteries and tendons, called upon the defendant for treatment. The defendant was a physician and surgeon residing in a country town of about twenty-five hundred inhabitants, and had no experience in surgery beyond that usually had by country surgeons. The result of the treatment not being satisfactory, suit was commenced for malpractice in dressing and caring for the wrist. Upon the trial one expert called by the plaintiff testified that he did not think the average country surgeon would be likely to possess the requisite skill to care for this wound. The evidence of the experts regarding the propriety of the treatment given the injury was conflicting, some testifying that it was properly treated, others the contrary. The court, upon the principle in consideration, instructed the jury that "the defendant, undertaking to practise as a physician and surgeon in a town of comparatively small population, was bound to possess that skill only which physicians and surgeons of ordinary ability and skill, practising in similar localities, with opportunities for no larger experience, ordinarily possess; and he was not bound to possess that high degree of art and skill possessed by eminent surgeons practising in large cities, and making a specialty of the practice of surgery. He is not responsible for want of success, unless it is proved to result from want of ordinary care and attention, and then only to the extent of the injury caused by his want of skill and neglect, nor for the whole consequence of the particular

The jury, applying this instruction to the evidence before them, found a verdict for the defendant. The plaintiff, being dissatisfied, appealed, but the trial of the case, including the instruction of the trial judge, from which the above quotation was taken, was approved by the supreme court.

The case of Hattorn vs. Richmond* is somewhat peculiar, and one in which there is considerable law. The plaintiff, whose leg was fractured, sent for his regular physician. The regular physician declined to take the responsibility of reducing the fracture and laid the leg on a double inclined splint, to make the patient as comfortable as possible. On the following day the defendant was sent for and reduced the fracture. The regular physician continued to attend the case nearly every day for about twenty-two days, when another physician was called to take his place. The defendant, who had reduced the fracture, did not call again until five days after the operation, and then only by reason of a letter written him by the regular physician at the request of the patient's friends, especially requesting him so to do. At the time of making this call the patient did not seem to be dissatisfied with the services rendered by the defendant and made no claim of improper treatment. For what purpose he was called, or what he did, if anything, while there, the report of the case does not show. It seems that the leg was bandaged too tightly, and as a result the injury followed for which suit was brought. The defendant claimed that he was only sent for to take charge of setting the leg with the assistance of the regular attending physician, and that he did this properly, and then left plaintiff in the hands of the regular physician as his patient, without any expectation of again visiting the case unless specially sent for. All the surgeons called on the part of the defendant testified that the surgeon applying the dressing in any such case could not tell whether the bandage might prove too tight or too loose, but that this matter must necessarily be left with the attending surgeon, whose duty it was to examine carefully in reference thereto, and adjust the dressing and bandages as might be needed. No evidence was offered to contradict this.

It was conceded and treated in the trial that the course taken with the limb in the interval between the time defendant left the patient after he had finished dressing the injury and his second visit, five days later, was lacking in proper and ordinary skill and care.

In the matter of general professional requirements, the trial judge instructed the jury, in effect, that the defendant would be held to possess such knowledge and skill and exercise such care and judgment as that ordinarily possessed and exercised by doctors in the same general neighborhood and in the same general lines of practice; and that they should determine from the evidence whether the defendant did possess such knowledge and skill; and if they decided this question in the affirmative they should determine whether he used ordinary care in dressing the leg. This instruction the supreme court held to be correct.

The trial judge continued with his instruction to the jury, charging them that if they found the defendant was wanting in the proper exercise of skill in the tight-ness of the bandage, still, if his employment ceased when he had set and dressed the limb, and the treatment of the case fell to the attending physician, and it was the duty of the attending physician to discover that the bandage was too tight and to loosen it and redress the limb, and if by such proper loosening and redressing of the limb the injury of the tight bandage could have been prevented, then the defendant would not be liable for the injury. The supreme court denied the correctness of the instruction upon the following grounds: It will be observed that this instruction assumes that the bandage was negligently applied by the defendant. From this fact it will necessarily follow that the improper application of the bandage will begin to exert an injurious influence upon the limb from the moment it is applied, and therefore it would be manifestly unjust to assert that the defendant is not liable for the injury inflicted by this negligently and improperly applied bandage during the ten or, perhaps, twenty-four hours which must elapse before the attending physician can detect the improper bandaging and give relief.

Moreover, the court declined to intimate whether it would relieve the defendant from liability for the injury resulting from his improper bandaging after the time when the attending physician should have discovered that the bandage was too tight and given relief, or whether it would hold him liable for all damages resulting from his own improper bandaging and the assistant's negligence in failing to readdle the bandage. The judgment rendered for the defendant in the original trial was accordingly reversed and the case sent back for a new trial. In view of the open question left by this decision, it can hardly be considered prudent for a surgeon to dress an injured member and leave all subsequent treatment to the regular attending physician, relying upon him to correct any inadvertency which may have attended the original operation or treatment.

(To be continued.)

Overexcitability, Hypersensitiveness, and Mental Explosiveness in Children.—Dr. T. S. Clouston (Scottish Medical and Surgical Journal, June) says that the vagueness and variety of these conditions have prevented them from being systematically described. They are all referable to the brain cortex as their immediate loci, and almost all are pathogenetically states of deranged reactivity of the neurones of the higher regions of the brain. They are none of them dependent on febrile states, though in some of them the temperature may be a little raised. There is no real pyrexia in a proper sense, the elevations, if present, being accountable for by increased and somewhat uncontrolled nerve action. In all of them the higher inhibitory centres are weakened absolutely or relatively to the amount of energizing they have to control. He does not include among them conditions of delirium or unconsciousness, or night terrors; nor does he put the systematized motor explosions or convulsions, limited or general, in their category, or class them as out-and-out "mental diseases." They are not within the legiti-

* Hattorn vs. Richmond, 48 Vt., 557.
mate bounds of "temper," "peculiarity," or "temperament," in any strict and proper sense of those terms, vague as they are in meaning, and many and varied as are the psychological sins which those terms are made to cover. They have no necessary relation to congenital mental weakness or defect in the ordinary sense. Yet in many cases they are brain cousins to certain kinds of delirium and convulsions, they often have a spice of insanity about them, and they frequently look exceedingly like uncontrolled bursts of temper or wickedness. They can mostly be traced, as to their ultimate cause, to hereditary and congenital peculiarities. There may be many exciting causes for their appearance at any special time, but the predisposing cause is nearly always defect in the subtle and most obscure process of central nerve development in the child.

The first of those morbid states to which the author directs attention is a simple hyperexcitability; an undue brain reaction to mental and emotional stimuli. This may come on at any age, from three years to puberty. The child becomes ceaselessly active, but without changing in its activity, it is restless and so absolutely under the domination of the idea which has raised the excitement that the power of attending to anything else is for the time being gone. When any joyous or pleasurable news is heard or any new toy is got, or any striking object is seen—a new dog or pet, or a child friend—there results a wild delight, quite incommensurate with the cause, even for a child. It laughs, jumps, makes faces, throws itself on the ground, makes senile choristic movements of its body, and gives way to a sort of delirium of pleasure. In a short time it can neither be quieted nor its attention directed to anything else. This state is, in fact, a morbid exaggeration of the normal state of a healthy child of a nervous temperament. But it comes on in bursts in this exaggerated morbid form. The liability to it lasts for perhaps a few months or a year, the child during this time tending to get thin, not sleeping soundly, and not getting on with its education if that has begun. It seems to consist essentially of a sort of automatism of the emotional centres in the brain uncontrolled by the centres of inhibition. Those emotional centres must be hyperesthetic, and the motor equivalents and expressions explosive during such an attack, for an attack of nervous disease it is in many cases. The eye is bright and restless, the pulse quickened, and the general state one of unhealth.

A somewhat analogous condition is sometimes met with in children of from three to ten where they become subject to stimuli, not mental as those last described, but from the senses—particularly from the special senses—in too keen a degree. Any loud noise will startle them and "upset" them badly, or will put them into a condition of trembling and terror. Any unusual or terrible sight will cause sleeplessness, tendency to nightmare, and a condition bordering on hallucination. Such sights they revivify and "visualize" very intensely, to their great distress and the disturbance of everyone near them. At such times the children become sometimes intensely sensitive to pain of any kind or to unusual impressions on their skin, crying at every slight cause of that kind and not stopping their weeping soon and forgetting all about it as the healthy child does. The author has never seen such a condition of oversensitiveness and overreactiveness from nerve excitation in the senses of smell or taste. But certainly impressions of heat and cold may have such accentuated effects. It seems as if in such cases it was the special sense centres in the cortex that had become hyperesthetic, just as the emotional centres had become hyperesthetic in the cases previously described.

Another state which is certainly of the nature of disease is that where children become for a time so overimaginative that they can not distinguish between their objective experiences and their subjective images, and where, without stimuli from without, mental or bodily, they conjure up fancies so vivid that they mistake them for realities and talk about them accordingly. Of course all children, especially the sensitive and clever children of neurotic ancestry, have this tendency in a large degree, but while free from actual disease they can, by a slight effort, distinguish between the real and the imaginary. No doubt, the author says, all children are more or less liars physiologically, but those of whom he is speaking are automatic and quite involuntary tellers of stories which have little or no foundation in fact. The intensity and actuality of their imaginations are greater than is consistent with a normal working brain. The normally limited power of young children to come to sound conclusions about things from the facts at their disposal is in those he is describing reduced to the vanishing point, and this condition in its marked and morbid form comes and goes. At times their brains seem capable of realizing facts and real impressions, and at other times they are simply the slaves of their overexcited imagination. No doubt, in certain matters and on certain occasions all children may exhibit such a peculiarity without any brain condition that it would be proper to call disease, but when it gets to be the habitual state for several weeks or months and then passes off, one must conclude that some change of brain working of a morbid kind had taken place through which such mental effects were produced.

The next variety of this general class of cortical explosiveness is one which the author believes to be comparatively frequent. Its general features are as follows: A child of between four and ten, of nervous temperament, bright, attractive, forward, and clever, has worms, or a bad cold, or some child complaint which reduces the nutrition and interferes with growth. She—for it is more common, he thinks, among girls—becomes capricious in appetite, irritable in temper, and has disturbed sleep and troubled dreams. Then comes a stage of what seems like very bad temper. The child resists authority, is driven wild by coercion, and when so roused assumes a maniacal and furious look. In that state she will fly at those who contradict her or who will not comply with her requests, is dull and stupid at lessons, to which she is most averse, and is strange and perverse in her likes and dislikes to persons, foods, and inanimate things. She expresses suspicion and even hatred of mother, governess, and sisters, is profane in language, and often prefers an unnatural solitariness of habits. Such a state is not, however, constant. The child returns to an affectionate and obedient mood, but even then is changed in certain ways from its normal self. Very little contradiction or discipline, and sometimes no such outward source of disturbance, is needed to rouse the demon in her again. When at her worst she looks really maniacal, scarcely can be roused to answer ordinary questions, her power of attention and learning lessons is gone, and no "motives" whatever act as they should do. She is all the
time thin and getting thinner, looks an unhealthy color, often acquires tricks of picking the nose, grinding the teeth, scratching the skin, or making faces.

The author once saw a girl of seven with the symptoms described in a marked and aggravated degree. There was no suspicion of imbecility and no proof of epilepsy. The child was bright and gay when well, but impulsive and wayward when ill, and for a few hours almost every day she was a perfect little demon. But at night she would be effusively affectionate and as charming as possible. Learning lessons was, of course, out of the question. Of anything like discipline or comfort to those about her there was none. Worms were suspected, and she was treated for them, but none existed. Tubercular meningitis was suspected, but there was no proof of it. She was put on a purely milk and farinaceous and fruit and cod-liver oil diet—she had been rather a ravenous flesh eater. A motherly, sensible Scotch nurse was recommended instead of a governess, the mother being young and inexperienced. A daily routine of exercise in the fresh air and suitable play were prescribed, and that she should be read to from not too imaginative and exciting books, and forty-five grains of bromide of potassium were given daily with a minute quantity of arsenic. For a month only a few good effects resulted, but she in no way got worse. At the end of that time she began steadily to improve. She slept better, she became less subject to her paroxysms of irritability and temper, and she got to like her new diet. In six months she had almost entirely recovered, and became a sweet, intelligent, fairly manageable child, with no such morbid and explosive "temper" as previously described, a comfort and attraction at home instead of being a source of the deepest anxiety. The bromide agreed perfectly all the six months it was taken, and acted manifestly as a diminisher of irritability and a promoter of nervous stability. Its permanent use was stopped when she got over the paroxysms, but a dose was given every day for a week when there seemed any unusual temper or excitability.

As to prophylaxis, much may be done by a physiological régime of life, and a nourishing but not too stimulating dietary that will steady the neurotic and explosive tendency in such a case.

In both sexes cases of persistent ungovernable sexual excitement occur through masturbation, several years before normal puberty comes on. No doubt in some of those cases there are local sources of irritation and excitement, but in most of them the source of the unnatural excitement is central and cortical. So far as can be made out, it is not attended by the normal mental sexual imaginings of full development, but has more of an automatic character. It is accompanied in many cases by most depraved sexual language and a loss of all decency of conduct. It seems like an outburst of energy on the part of those centres in the brain which preside over the reproductive functions before the organs and apparatus had come to maturity. In two cases it seemed to the author as if animal sexual habits had been "reverted" to, such as attempts to lick and smell the sexual organs of the opposite sex. One great difficulty, however, was to find out how far such practices had been taught such children by vicious elders. The author has certainly seen in children morbid outbursts of what in older people would have been called "immorality" and attempted non-sexual crime, developing like a disease and passing away in a few weeks or months, leaving them mor-}

ally as they had been before. He quotes several cases in illustration.

The author thinks that this whole class of cases has the common characteristic of an explosive condition of the nerve cells in the higher cortex very analogous to the state of the motor cortex in ordinary epileptics. The catalepsism of the cells is morbid. In the rapid and marvelous development of the brain in childhood these cells not only multiply fast in number, but undergo a process of gradually becoming more stable in action. Where there is a hereditary tendency to neurotic conditions this process or nerve-steadying certainly seems not to go on satisfactorily in certain children, and an irregularly explosive tendency results. We know now, too, from Flechsig's observations, that in childhood new strands of fibre connections are constantly being formed and opened up between the great cell areas in the brain. No doubt every such connection that is completed stirs up such cell areas to new activity by bringing them into relationship with other functional areas. The inhibitory apparatus has to be strengthened with the widening of the areas of possible work but also of possible disturbance. All nerve cells are normally explosive in action in a certain way. The physiological explosiveness of cortical nerve cells has to be prevented from becoming pathologic convolution, either motor or mental.

So far as the author's experience of drugs goes, he has found the bromides by far the most effective in restraining normal nerve-cell action from assuming pathological forms. They must be given judiciously and with reference to the age of the patient, the acuteness and the nature of the symptoms, and the effects of the drugs in each case as seen by a skilled observer. They must often be given fearlessly in large doses up to the point when the symptoms of bromism are beginning to show themselves. One thing is certain, if they are to do any real good they must be given for long periods. Tonics and food medicines are given at the same time as the bromides, and the diet must receive never-ceasing attention. Milk will be found the sheet-anchor in dieting all such neurotic children. Environment too, fresh air, suitable amusements, companionship, control, employment must be looked to, and the schoolmaster must be regarded for the time as an aid to treatment and so under the doctor's orders.

Such an explosive brain need not remain uneducated, but it must receive its education in a physiological and medical fashion.

Red Light as a Therapeutic Agent.—The Lancet for June 10th says that in our conscious superiority to our forefathers we have been used to look with contempt on their practice of treating cases of small-pox by means of red light in the form of red blinds, curtains, and coverlets, but with our present knowledge of the chemical and physical action of the different rays of the spectrum and the influence of light and darkness on life in its highest and lowest manifestations we may have felt a suspicion that, whatever the theory of the mediaeval physicians, their practice may have had a scientific basis. In the last number of the Zeitschrift für Krankenpflege we find that it has been tried, and apparently with remarkable results, in the treatment of measles. A child, eight years of age, having sickened with an attack of measles of more than usual severity, was on the second day brought under the influence of the rays of least refrangibility, the windows being fitted with
red blinds and a photographer’s lamp with an orange-yellow globe being used for artificial light. In three hours the rash had disappeared, the fever had subsided, and the child was playing cheerfully, complaining only of want of light. The blinds were consequently removed, when three hours later the medical man was summoned to find that the eruption and fever had returned and the child was weak and prostrated. The red light having been resumed, the rash disappeared in little over two hours, as did the fever, this time permanently. In two more days the cough had ceased and the child was well in every respect. The brother and sister and a fourth patient infected from the first case were treated in the same way and with like success. In the great epidemic of small-pox in 1871–72 some cases were reported as having been kept in dark rooms with great benefit, especially as regards the pustulation and pitting. Clearly, what virtue there may be in this method lies in the exclusion of actinic rays, and the substitution of red or orange light for total darkness has obvious advantages, as in the case of photographic manipulations.

A Simple Method of Reducing Shoulder Dislocations by Manipulation.—Miller (Scottish Medical and Surgical Journal, May; International Medical Magazine, June) commends, as almost invariably successful, a simple method of manipulation for subcoracoid dislocation. The patient is seated, the arm grasped at the wrist and above the elbow and flexed to a right angle at the elbow. An assistant stands at the other side of the patient and steadies the scapula with both hands. The arm is then carried carefully outward and upward with outward traction until it is at right angles with the body. This procedure is designed to relax the subscapularis and deltoid, to unlock the neck of the humerus from the deltoid edge, and to bring the humeral head in close apposition to the glenoid cavity. As soon as the muscles are felt to relax, an internal rotation of the humerus, produced by dropping the hand, will cause the articular head to glide into place. The additional aid of an anaesthetic, of free circumsision to enlarge the rent in the capsule, or of pressure, by the thumb and fingers in the axilla, upon the head of the humerus, may be required. While these procedures have been successfully employed by many surgeons in combination with other methods, the author claims to have systematized them upon a scientific basis.

New Method of Inducing Premature Labor.—Spinelli (Archivio italiano di ginecologia, December, 1898; International Medical Magazine, June) asserts that his method can be performed by the general practitioner; no special instruments are necessary, and it starts labor in two or three hours with no danger. The patient being prepared for operation, the posterior lip of the cervix is seized and the cervix dilated with a dilator, if necessary, to admit one finger. The finger is crooked and carried up until the membranes are detached from the posterior surface. A yard of gauze saturated in ten-per-cent. ammonium ichthyolate and glycerin is then passed up on the finger and digitally pushed up higher and higher, care being taken not to rupture the membranes. Nearly the whole of the gauze can be introduced. The vagina should be plugged with sterile gauze and the patient put to bed. Pains begin very soon after the introduction of the gauze, and labor comes on rapidly.

Proceedings of Societies.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Meeting of April 5, 1899.

The Vice-president, Dr. Charles E. Quimby, in the Chair.

The Importance of an Operation in the First Stage of Thrombosis of the Sigmoid Sinus; with a Report of Three Cases.—Dr. Gorham Bacon read this paper. (See page 7.)

Dr. Emil Grupping said that the paper had presented the following symptoms of sigmoid thrombosis—viz., carache, fever, chill, and discharge. According to some, pyemia did not necessarily mean thrombosis of a vein, it being held that there might be direct absorption of pyogenic organisms from the middle ear. It was for this reason that the opening of the mastoid was performed first. The pupils of Schwartze had led astray a great many, because of their erroneous statement that the sole feature of the operation was the laying open of the mastoid antrum. This was only one feature of the operation. In these cases one found tenderness early not only over the antrum but over the tip. It was the latter which showed the extension of the mastoid disease downward. In New York this operation of Schwartze’s had been developed without deviating materially from the original method. No one could deny that Schwartze was the great pioneer in this field. The operation on the antrum, as performed in New York to-day, was not simply the opening of the mastoid antrum, but the opening up of every cell that might be involved, and the exploration of the sigmoid sinus and the roof of the antrum. When such a thorough operation had been performed, and in spite of it there were chills and fever, the diagnosis of sinus thrombosis was more justified, and the operation for this condition should be at once undertaken. The wall of the sinus would be found thickened, and perhaps there would be granulations on it. Very often these granulations were a protecting coat, and hence the scraping away of them was not always advisable. Mere thickening of the adventitious coat of the sinus did not necessarily indicate that the intima was affected, and that there was a thrombosis; on the contrary, under such circumstances there was usually no thrombosis. In those cases in which the thrombosis occurred at an early stage the wall would be found friable and easily permeable. There might be a very small thrombus, and still the symptoms be very severe. He was of the opinion that the extent of the clot had nothing whatever to do with the severity of the case. A small thrombus which did not entirely fill the lumen of the vessel was often more dangerous than a well-formed clot completely filling the canal, especially if it contained streptococci. The aspirating needle was of no use in these cases; the sinus must be compressed below, and a clear cut made into it. Koerner, one of the most scientific workers in this field, had said that in many of these cases of fever and chill there was no thrombosis, and he had expressed the opinion that there was an osteopelphitis—a septicemia, and not a thrombosis of the sinus. It would obviously be very wrong to ligate the sinus when there was no thrombus present. On the other hand, Leukart had asserted that
whenever there was chill with high fever in these cases, thrombosis was present, even though it might escape detection. The bulb of the jugular vein was often overlooked in post-mortem examinations, yet it was quite common, according to this observer, to find the clot at this point. This authority took the view that in the presence of high fever and chills, where other disease could be excluded, ligation should always be done, even though the thrombus was not discovered. Theoretically this would seem to be the correct position. It was especially difficult, even after a thorough operation on a child, to say that there was a thrombosis simply because of the existence of fever and chills. A case was cited in which the fever and chills were proved, by the administration of quinine, to have been the result not of a thrombosis, but of malarial infection.

Dr. Frederick Whiting said that when Zaufal in 1880 had first suggested that when a clot existed in the sigmoid sinus, although it might have undergone disintegration, there was a possibility, if the jugular vein were tied and its suppurative contents removed, that recovery would take place, the idea had been received with a great deal of incredulity on the part of the medical profession. Up to that time these cases had been diagnosed so late in the disease that they had been regarded as “inoperable.” In 1884 Zaufal had done the first operation of this kind, with an absolute ignorance of the proper technics, and without antiseptic precautions. As the case had promptly terminated fatally, it had been some time before the operation had been again advocated. But since that time our knowledge of the symptomatology and the technics had been greatly enlarged, and there had been many successes, both abroad and in this country. Many of these successes had been achieved by the reader of the paper of the evening. At the present time, it seemed as though the operation was deferred longer than was desirable. The first stage of sinus thrombosis was that in which there was phlegmon of the sigmoid and lateral sinuses, with a fibrinous clot that had not yet undergone purulent liquefaction. The second stage was that in which purulent liquefaction occurred. In the first stage of sinus thrombosis the prognosis was absolutely good if the patient was not yet septic and his vitality was good. When the case passed into the beginning of the second stage the patient was septic and was not in a favorable condition for operation. In the third stage of sinus thrombosis peripheral and central embolic metastases took place, and the outlook from operation was exceedingly gloomy. Two authorities had made themselves conspicuous by advocating avoidance of operation in the first stage of thrombosis, preferring to wait until it was positively known that the thrombus was infected. But the very fact that there was infective inflammation of the bone, extending into the vessels connecting with the sinuses, seemed to the speaker sufficient to prove that the clot was infected. It did not follow, of course, that this infection might be sufficient to cause a breaking down of the thrombus. Usually there was a local central infected focus. Hesler was one of those who advised postponing operation until it could be proved by microscopical and bacteriological examination that the clot was infected. Such a clot might be primarily infected, and the very fact of making repeated punctures for the withdrawal of blood for such an examination would probably be sufficient to result in its disintegration. The needle might be inserted in twenty places and yet not happen to reach the small septic focus. It was evident, therefore, that even an examination of this kind could not be looked upon as conclusive proof of the infective or non-infective character of the thrombus. On the other hand, Koerner, the highest authority on purulent and infectious disease of the cranial cavities, had made the statement that an operation should be resorted to just as soon as the diagnosis was made.

Dr. J. H. Woodward congratulated the reader of the paper on his great success in the cases reported. The importance of early operation in sinus thrombosis must be evident after the remarks of the preceding speakers; to his mind, not only the early operation but the one in the second stage of sinus thrombosis was desirable. It was generally held that infectious infarction of the lung was a fatal malady, yet authentic cases on record in which recovery had taken place. The pyemic temperature and chill were, of course, significant symptoms, but they might be present, as had already been said, without any thrombosis. Last year he had reported to this society a case of cerebellar abscess terminating fatally. Prior to death there had been a pyemical temperature and well-marked rigors. The autopsy had revealed no thrombus in the sigmoid, or any other sinus. Recently he had operated in a case of purulent discharge from the ear which had lasted for many years. The last relapse had occurred in February, and Dr. Woodward had first seen the patient on February 21st. Three days before this the first chill had occurred, and during the week previous there was considerable pain in the region of the mastoid. The temperature was 103° F.; there was purulent discharge from the ear with bulging of the membrana tympani, and the patient was decidedly stupid. There was tenderness in the region of the junction of the sigmoid and lateral sinuses. Under chloroform anaesthesia the speaker made an incision along the whole extent of the membrana tympani, but very little pus escaped. This incision was made because a more radical operation could not have been undertaken that afternoon. The next morning the radical operation was done. This revealed the presence of an extradural abscess. There was no sinus thrombosis, and the sinus pulsed synchronously not only with the heart, but with the respiratory movements. This patient made an uninterrupted recovery. Not long ago the speaker had operated upon a child of two years and a half by opening the mastoid antrum and evacuating a deep cervical abscess. On the day after the operation the temperature was 105° F., but it subsided with the reduction in the inflammation which had existed in the opposite tympanum. When the tip of the mastoid was involved, he said, one might be misled into thinking that the sinus was involved. A positive diagnosis could be made in many instances only by an exploratory operation. This exploration should extend, if necessary, to the cerebellum or the spheno-temporal lobe. Infective thrombosis of the sigmoid sinus had been diagnosed by excellent clinicians as typhoid or malarial fever, so that the physician should be constantly on guard in such cases. The cases reported in the paper this evening, it should be noted, were acute, and quite early symptoms of mastoid involvement had been shown. He was of the opinion that acute purulent inflammation of the middle ear usually led early to more or less inflammation of the neighboring structures in the mastoid region. The best way to prevent sinus thrombosis was by attacking these cases early, doing a radical operation. It seemed to him that too much importance was laid upon the simple incision of the mem-
brana tympani. When there was reason to believe that the mastoid cells had been enroached upon the mastoid antrum should be laid open, and treated thoroughly and radically. He had known the wound to heal within ten days under proper management. In cases of chronic suppurative otitis media also he believed in an early and radical operation as a positive and successful prophylactic measure. Macewen had given the clearest idea, he thought, of the lines on which these operations should be done, and if they were followed there was but little danger of infection of the interior of the cranium.

Dr. C. E. Quinby said that while the success of the operation might depend upon the surgeon, the opportunity for successful operating seemed to depend very largely upon the physician. It was not uncommon to meet with suppuration of the ear associated with very small rupture of the drumhead, and he would like to know if incision and irrigation constituted the proper treatment here.

Dr. Bacon said he was of the opinion that free incision was an important and desirable procedure. Where the drum membrane had been perforated spontaneously the opening was usually very small, and in such cases, unless a free incision was made, mastoid involvement was very prone to occur. He took exception to the remark made by Dr. Gruneen to the effect that thickening of the wall of the sinus and the existence of granulations did not usually indicate the presence of a thrombus, for, in all three of the cases reported in the paper, thickening of the sinus wall had been the condition found at the operation. The division of the disorder into stages was certainly convenient, even if perhaps not strictly scientific. If the patient's condition was favorable, and he was not likely to die on the table, he would favor operating, even in the second stage. In only one of the three cases reported had there been marked swelling of the entire wall of the external auditory canal.

The Bearing of the Zeitgeist on Insanity.—The Tri-State Medical Journal and Practitioner for May, in an editorial on The Increase and the Modern Causes of Insanity, quotes the following apposite remarks of Dr. John H. Girdner from the North American Review: "The struggle for existence, modern inventions, steam and electricity, and the mad rush for wealth, result in ever-increasing demands upon the brain and nervous system. And under this strain, many who have congenital or acquired defective nervous organizations become insane, just as the same class formerly did as a result of fear and brooding over theological problems. "The insane are not now tormented by the devil and his imps, but telephones and phonographs are continually ringing in their ears. Others suppose they have steam engines in their heads, and many imagine they are persecuted by men of large fortunes or of great political power. Formerly, those who were afflicted with delusions of grandeur were prone to imagine themselves to be the Saviour of the world or the Virgin Mary, or some eminent saint. Now they are more apt to think themselves to be great inventors or powerful politicians, or the possessors of untold wealth. The delusions of the insane always take form and color from the questions and problems which are most absorbing at the time."

The Necessity of Individualism in Medical Practice.—Dr. William Osler (Albany Medical Annals, June), in an address to the students of the Albany Medical College, said: Be careful when you get into practice to cultivate equally well your hearts and your heads. There is a strong feeling abroad among people—you see it in the newspapers and you see it in the Associated Press dispatches—that we doctors are given over nowadays to science, that we care much more for the disease and the scientific aspects of it than for the individual. I don't believe it, but at any rate, whether there is that tendency or not, I would urge upon you in your practice in the future, to care particularly for John and Elizabeth, as George Eliot says—but I will not add especially for Elizabeth—to care more particularly for the individual patient than for the special features of the disease. I am sure all of you must feel, even those of you who have only been a single term in the professional work, that you have entered upon a profession that appeals both to the heart and to the head. Dealing as we do with poor, suffering humanity, we see the man unmasked, exposed to all the frailties and weaknesses, and you have got to keep your heart pretty soft and pretty tender not to get too great a contempt for your fellow creatures. The best way to do that is to keep a looking glass in your own hearts, and the more carefully you scan your own frailties the more tender you are for the frailties of your fellow creatures.

A Clever Rondeau.—Practical Medicine for June quotes from the Indiana Medical Journal the following very clever rondeau, which, we believe, originally appeared in the Boston Medical and Surgical Journal. We venture, however, with apologies to the unknown author, to make an emendation, as the form is not strictly in accordance with that of the rondeau after Voiture's generally accepted model, which demands in the alternation of rhymes the following order—a, b, b—a, a, b (not a, b, b, as in the original of the following verse):

A Misconception.
"I can't conceive," she archedly cried,
"Wherein you men can longer pride
Yourselfs from female rivals free,
For surely we have grown to be
Your peers in every human stride.
"That is a truth that none may hide;
So why you men will not decide
To recognize the new degree
I can't conceive."

"Now entre nous won't you confide
And tell me true, all jokes aside,
What difference the world can see
Between your manly self and me?"
"To tell you truly," he replied,
"I can't conceive."  

Deaths under "Christian Science."—Reports of deaths more or less directly due to "Christian Science" are coming in so rapidly from all parts of the country that the patience with which the country endures the crimes of the would-be exorcists is simply amazing. Notes of protest are, indeed, to be heard coming from various directions, but most of them are sounded by organizations of little influence or authority, like the Medico-legal Society of this city, or in courts of limited jurisdiction and unimpressive powers. The great medical associations, State and county, content themselves with occasional ridicule of the "Scientists" and their dupes, but they do nothing effective, while the various legislatures ignore altogether this danger to the life and health of the whole population of the country and devote their energies to matters many of which are of much less public importance. Meanwhile the high priestess of ignorant credulity informs her propagandists only long enough to make affidavit that she is not yet dead, and, having demonstrated her continued existence, proceeds industriously with the appointment of new book agents and the acquisition of more wealth. All this is amusing enough in its way, but it is also humiliating and dangerous. Every "Christian Scientist" is a potential centre of infection for bodies as well as minds, and that the victims of this infection are many is shown every day that passes.—New York Times.

The William F. Jenks Memorial Prize.—The College of Physicians of Philadelphia announces that the fifth triennial prize of five hundred dollars, under the deed
of trust of Mrs. William F. Jenks, will be awarded to the author of the best essay on The Various Manifestations of Lithemia in Infancy and Childhood, with the Etiology and Treatment. The conditions annexed by the founder of this prize are that the "prize or award must always be for some subject connected with obstetrics, or the diseases of women, or the diseases of children"; and that "the trustees, under this deed for the time being, can, in their discretion, publish the successful essay, or any paper written upon any subject for which they may offer a reward, provided the income in their hands may, in their judgment, be sufficient for that purpose, and the essay or paper be considered by them worthy of publication. If published, the distribution of said essay shall be entirely under the control of said trustees. In case they do not publish the said essay or paper, it shall be the property of the College of Physicians of Philadelphia." The prize is open for competition to the whole world, but the essay must be the production of a single person. The essay, which must be written in the English language or, if in a foreign language, accompanied by an English translation, must be sent to the College of Physicians of Philadelphia before January 1, 1901, addressed to Richard C. Norris, M. D., chairman of the William F. Jenks prize committee. Each essay must be typewritten, distinguished by a motto, and accompanied by a sealed envelope bearing the same motto and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay. The committee will return the unsuccessful essays if claimed by their respective writers, or their agents, within one year. The committee reserves the right not to make an award if no essay submitted is considered worthy of the prize.

The Italian Society of Laryngology, Otology, and Rhinology will hold its fourth meeting in Rome in October, under the presidency of Dr. Giuseppe Gradenigo, of Turin.

The Orleans (Louisiana) Parish Medical Society.—At the meeting of June 9th Dr. C. Jeff. Miller reported a case of a large fibroid of the uterus and a fibroid of the ovary in the same patient. Supravaginal hysterectomy was performed. The fibroid of the uterus weighed six pounds and three quarters, that of the ovary three pounds and a half. Another case of interest was the removal of the vulvar tissues for extensive epithelium in a colored woman only twenty years of age. The woman's age rather suggested a chancreoid ulceration, but the clinical picture was striking, and two specimens were pronounced epithelium by the pathologist. The woman had never borne a child.

A New Italian Pharmaceutical Journal.—The Annali di farmacoterapia e chimica is the title of a journal which is the continuation of the Annali di chimica applicata alla medicina, of the Rivista di chimica medica e farmaceutica, and of the Annali di chimica e farmacologia. It is edited by Professor Bufalini, of Florence; Professor Baldi, of Pisa; and Professor Corronedi, of Sassari, and published in Milan.

The Medical Society of the State of Colorado held its twenty-ninth annual meeting in Denver on June 20th, 21st, and 22d, under the presidency of Dr. W. A. Campbell, of Colorado Springs. The address in medicine, on Arteriosclerosis, was by Dr. Robert H. Babcock, of Chicago; that in surgery, on The Satisfactory Results Obtainable by Operative Treatment in Disfiguration of the Face and Ears, by Dr. John B. Roberts, of Philadelphia.

Criticism in an Epitaph.—An esteemed Canadian correspondent writes to us as follows:

"The death of Jane, Smith white of John. Smith aged 36 years Whose life Was husked a Way by Dr. Scalpel on the 16th of February 1852

With out one moments Warning
With Oloriform and
the Wife lost my life
and O my infant dauter
Was made a slauter the
SCull Been put a sunder"
caine, tar, etc., might all be useful in one form or another.

A Modification of Whitehead's Operation for Hæmorrhoids was described at the same meeting by Dr. Earle, of Baltimore. It consisted in clamping the tumors by sections, beginning at an incision in the fourchette, where a primary incision was made to determine the depth at which to place the clamp. After the removal of the tissue above the clamp piece-meal, a continuous suture, beginning at the primary incision, was inserted around the clamp. When the first section had been cut away and sutured, the clamp was removed and the suture drawn taut; then the clamp was again put in position and kept there until the whole anal circumference had been treated. He stated that he had given this method a thorough trial, and unhesitatingly said it was the safest, the easiest, and by far the best method that he had ever tried. The operation was practically bloodless, and healing by first intention was secured. The convalescence was complete at the end of a week. Dr. Earle demonstrated his method of operating at St. Anthony's Hospital.

The Act of Defecation was the subject of a paper by Dr. Thomas Charles Martin, of Cleveland, read before the same meeting. He said that a knowledge of the anatomy of the rectum was necessary to form an appreciation of the physiology of defecation. The bundles of circular fibres which constituted the muscular element of the rectal valve belonged to the same mechanism and had the same function as those which formed the ental sphincter. It was the function of the normal rectal valve to "beneficently" retard the descent of the faces, and it was obviously true that it might be the special province of the valve in certain other than normal conditions to "maliciously" obstruct the descent of the faces. His experience convinced him that a perfect knowledge of the rectal valve constituted the key to an understanding of obstipation, rectal stricture, and their sequellæ.

Constipation Considered from the Standpoint of the Proctologist was the title of a paper read at the same meeting by Dr. A. B. Cooke, of Nashville. He defined constipation as a diseased condition of the alimentary canal characterized by a modification of function which resulted in the pathological retention of fecal matter. He mentioned among the causes those springing from the violation of hygienic laws; defective innervation, expressed either in atonicy of the muscular coat of the intestine or in decreased secretion; sluggishness of bowel function; the habitual use of purgative medicines; mechanical obstruction; and painful affections of the anus. The relations between constipation and diseases of the rectum, he said, were intimate and noteworthy in that either might be the cause or effect, with reference to the other. Rectal reflexes came in for a fair share of consideration. It was the author's conviction that in a large proportion of cases constipation either originated in or was maintained by conditions situated in the distal ten inches of the intestinal tract. If this was true, he said, the notorious inadequacy of ordinary treatment was at once accounted for, and the duty of the proctologist in the premises became obvious.

Rectal Adenomata.—Dr. William M. Beach, of Pittsburgh, presented this subject at the same meet-

ing. He defined an adenoma as an hypertrophy of gland texture. He noted briefly the nature of these growths and the value of the proctoscope in their early diagnosis and treatment. He said there are two principal types of adenomata—the gelatinous, composed of elements of mucous membrane; and the mixed variety, consisting of mucosa and submucous cellular tissue. The adenoma with a long pedicle was benign, while growths with a broad base tended to malignity. By means of the old methods of examining the rectum, he said, it was well-nigh impossible to ascertain the situation of these growths of the upper rectum, but the newer proctology substituted exact methods in the diagnosis and treatment of non-malignant adenomata that were most gratifying to both the patient and the surgeon. A rectal adenoma might be hard or soft and contain the constituent elements of the mucosa and submucosa; these growths were benign or malignant; when benign in their origin, they might become malignant. Early recognition of them was of the first importance.

The Post-operative Treatment of Hæmorrhoids was discussed at the same meeting by Dr. J. R. Pennington, of Chicago. He stated that the success of a rectal operation depended quite as much upon the after-treatment as upon the operation itself. He used a tampon made by taking a piece of five-inch rubber tubing, about four inches and a half long, wrapping it with sterilized gauze until it was as large as desired, and then covered this tent with a special rubber covering. Before introducing the tampon he blew nasophene powder over the field of operation. It was introduced through a bivalve speculum. Among the advantages alleged for the rubber-covered tampon over the gauze dressings were these: It was neater; its removal was painless, as the granulations could not and did not penetrate or adhere to the rubber covering as they did to gauze or wool dressings; the tender granulation sprouts were not broken off during its removal, and hence there was little or no hæmorrhage, so that the wound was left better fortified against septic infection and the healing process was greatly enhanced; and there was practically no pain during defecation, a point of very great importance.

The New York State Examination.—The Examination Department of the University of the State of New York has favored us with the following statement:

| Total number of candidates in the May licensing examination | 131 |
| Rejected | 20 |
| Percentage of rejections | 15.27 |
| Percentage successful | 84.73 |
| Total number of honor candidates | 10 |
| Highest general average | 93.3 |
| Rejections in anatomy | 12 |
| Rejections in chemistry | 7 |
| Rejections in surgery | 3 |
| Rejections in pathology and diagnosis | 9 |
| Rejections in physiology and hygiene | 3 |
| Rejections in obstetrics | 3 |
| Rejections in therapeutics, practice, and materia medica | 9 |
| Rejections in one topic | 10 |
| Rejections in two topics | 5 |
| Rejections in three topics | 1 |
| Rejections in four topics | 3 |
| Rejections in five topics | 3 |
Original Communications.

REPORT OF THREE CASES OF MULTIPLE PISTOL-SHOT WOUNDS OF THE INTESTINE, WITH REMARKS.*

By GEORGE WOOLSEY, M. D.,
SURGEON TO BELLEVUE HOSPITAL; PROFESSOR OF ANATOMY AND CLINICAL SURGERY IN THE CORNELL UNIVERSITY MEDICAL COLLEGE.

I will briefly give the histories of these three cases on which we may base our remarks as to the general subject of pistol-shot wounds of the stomach and intestine, and the points of special interest suggested by these three cases. They all occurred in my service at Bellevue Hospital:

CASE I.—J. B., a man, aged forty-one years, was admitted on the evening of October 4, 1891, very shortly after having been shot at twice with a 38-calibre revolver. There was a wound of entrance in the centre of the left iliac region, and a contusion under the left nipple, due apparently to a bullet striking against some article carried in the pocket. There was but little pain or shock. Operation the same night, about six hours after the accident.

Through a five-inch incision a little to the left of the median line the intestines were removed and examined. Eleven perforating wounds were found in the small intestine and closed by Lembert sutures; the abdominal cavity was well irrigated and the abdominal wound sutured. There was but little blood or fecal matter in the peritoneal cavity, which was thoroughly washed out. The bullet was not found, though apparently it had taken an oblique course from left to right.

The diagnosis of penetration had been made by careful exploration with probe and finger after slight enlargement of the wound. During the next day the patient's general condition seemed good. After this the temperature steadily rose.

He sank as if from septic poisoning and died on the third day, about fifty-four hours after the accident, and forty-eight hours after the operation. The bowels had not moved nor had there been vomiting since the operation.

Autopsy by Dr. H. P. Loomis showed that the wounds were all in a section of ileum three feet in length. This part was somewhat distended and congested, but there was no evidence of general or progressive peritonitis. The eleven wounds were tightly closed and there were no others.

The bullet was found in the right iliac fossa.

CASE II was shown to the New York Surgical Society January 22, 1896, and the report published in the Annals of Surgery, April, 1896. I will therefore give the history as briefly as possible.

W. McC, a man, aged twenty-three years, was admitted December 21, 1895, at 10.30 p.m., immediately after being shot twice by a pistol of 32 or 38 calibre, held nearly in front and at close range. Before I saw him and commenced operating, five hours later, he had vomited frequently, had had one movement of the bowels, mostly blood, and had partly rallied from shock. At the time of operation he had great pain and was vomiting frequently. One bullet had passed through the left buttock and the other had entered the abdominal wall midway between the left anterior superior iliac spine and the umbilicus. A probe passed only as far as the muscle layer inward, downward, and backward. An incision in the left semilunar line met the track of the bullet just external to where it pierced the rectus muscle, through which a probe, introduced, showed the course to be more transverse than first supposed. Hence the first superficial incision was closed and a median incision was made from the umbilicus to the symphysis, to reach both sides of the abdomen. A moderate quantity of blood and clots and a small amount of fecal matter were found in the peritoneal cavity. The peritoneum was quite congested, and some serum was mixed with the blood. The jejunum and ileum, which were remarkably empty, were examined from end to end and presented sixteen perforations, most of them in the lower ileum, but some in the jejunum. Twelve perforations were closed by Lembert sutures, but, as four in the lower ileum were within two inches of one another, three inches of the intestine were excised and an end-to-end anastomosis was done with a Murphy button, to avoid stenosis or kinking and to save time.

Perforations were confined to the small intestine. The bullet was not found, and no time was wasted in searching for it. Throughout the operation large quantities of hot, sterile, normal salt solution were used for cleansing, to keep the bowels moist and warm, and to combat shock. The wound was closed except for a glass drainage tube in the lower angle extending into the pelvis. The patient made an excellent recovery; the Murphy button was passed on the ninth day, and the wound healed per primam, except for the point where the tube remained three or four days. The bowels moved first on the third day, and a movement of the bowels tended to cure the occasional attacks of pain or vomiting he had

CASE III.—A. K., a lad, aged nineteen years, was admitted December 5, 1898, soon after being shot in the abdomen by a 32-calibre pistol. He had severe pain and frequent vomiting, but no vomiting of blood. The wound of entrance was about midway between the axillary and iliac crest. A bullet entered, passed down and inward through the rectus muscle, and then was deflected about an inch and a half above the upper border of the iliac crest. The bullet could be felt beneath the skin an inch to the left of the median line and just below the free border of the ribs. An opening was made here, the bullet removed, and the track explored, showing it to be a penetrating wound, and also a perforating one, on account of the presence of fecal matter. Hence I was called and operated four or five hours after the accident. A six- or seven-inch incision from a little below the ensiform cartilage was made through the right rectus, an inch to an inch and a half from the median line, separating the fibres of the muscle. This incision was chosen because the course of the bullet indicated that most of the injury was on the right side, and the event proved the wisdom of the course, as the ascending colon was more easily reached. There were two wounds of the ascending colon, two of the transverse colon, and two of the stomach. The wounds of the stomach were very close to the great curvature, one on the anterior and one on the posterior surface. The latter, and one of the wounds

* Read before the Roosevelt Hospital Alumni Association, February 17, 1899.
on the transverse colon, opened into the lesser peritoneal sac and were found and sutured through small openings in the gastrocolic ligament of the great omentum. All the wounds were sutured by Lambert sutures. The small intestine was examined from the duodenaljejunal to the ileocolic junction, but no wounds were found.

In accordance with the suggestion in the report of the second case of the use of intestinal disinfectants, an attempt was made to introduce powdered salol into the intestine through the wounds, but it was found difficult and scarcely feasible to introduce it into the moist collapsed intestine. Large quantities of hot normal saline solution were used to cleanse the cavity of the small amount of blood and stomach and intestinal contents found therein. Gauze drains were introduced, as a matter of precaution, down to the foramen of Winslow, as the lesser peritoneal sac could not be so easily cleansed.

Interrupted silkworm-gut sutures, including all layers, continuous catgut suture of the peritoneum, and silk sutures of the skin were employed to close the wound.

During the next three nights the patient, suffering from thirst and a moderate degree of delirium tremens, got out of bed from one to three or four times a night, in the absence of the nurse, to search for a drink. Hence it was not strange, on dressing the wound on the fourth day, to find that the sutures had torn through and the wound was gaping in the middle, where the intestine was exposed, the upper and lower angles remaining closed. The delirium lasted about a week; otherwise recovery was uneventful, though there was some rise of temperature for the first few days, but no symptoms of peritonitis. No food by stomach for five or six days, rectal feeding being employed.

Twenty-four days after the first operation an operation was done to cure the hernia, opening the peritoneal cavity by prolonging the incision above and below. The intestines were found very adherent to the margins of the opening and were separated with some difficulty. The margins of the opening were pared to expose the rectus and the wound sutured as before, except that three or four stout silk sutures were required to relax the tension, and the separate skin sutures were omitted. In spite of some suppuration along the sutures, especially the tension sutures, the wound healed well and gave a firm cicatrix, though between the latter and the median line the muscle fibres seem to have atrophied, from the section of the fine nerve twigs supplying them. He was advised to wear an abdominal bandage, and was discharged cured February 9, 1899.

The following are among the points of interest suggested by these three cases:

In Case I death was evidently due to sepsis and not to peritonitis, for the symptoms were altogether those of the former and not of the latter. It was not one of those cases of general septic peritonitis in which the septic symptoms overshadow the peritonitic, for on autopsy such a peritonitis was not present. There was no peritonitis, unless the congestion and distention of the short length of ileum containing the eleven perforations are so called. It might have been better to resect these three feet of ileum, but it was before the days of the Murphy button, and resection of three feet of gut

followed by enterorrhaphy seemed a formidible operation. But where did the absorption of septic matter occur? Apparently it was a case of auto-septicemia from the putrid and toxic contents of this parietic area of the ileum, the toxines being absorbed by the wall of the intestine in general, and perhaps the raw inverted edges of the wounds in particular.

This suggested the giving of salol as an intestinal disinfectant in Cases II and III, and the attempt to introduce it into the gut through the wounds in Case III. The latter method of application is not practicable unless the salol is made into a kind of pill mass, and the use of an intestinal disinfectant may be merely theoretical, though apparently rational. As to whether and how far it may contribute to a favorable result, a larger experience would be required upon which to base an opinion. But if there is such a thing as auto-septicemia, intestinal disinfectants would suggest themselves as a rational treatment where the physical condition of the bowels precluded early catharsis.

In Cases II and III the bowels were remarkably empty. This may have contributed to the favorable result (1) by affording less material for intestinal purgative changes, and consequently less toxic matter for absorption, and (2) by reducing to a minimum the amount of fecal extravasation and thus rendering the danger of peritonitis less.

The large amounts of hot, sterile, normal salt solution used in Cases II and III had a twofold value—in flushing and cleansing the peritoneal cavity and in diminishing shock.

I have not found that evisceration, if gently done, added to the shock, and it enables one to cleanse the surface of the bowel and mesentery more thoroughly and is essential to the examination of the jejunum and ileum from end to end, so that no perforation may escape notice and thus entail a fatal result.

Where a short length of intestine is riddled with bullet holes it is generally recognized to be better to resect the part and make an end-to-end anastomosis with a Murphy button. This was done in Case II, where there were four holes in two inches of gut, and was found to save time as well as to avoid stenosis or kinking of the intestine. It might even have been advisable in Case I, but, as stated above, it was before the day of the Murphy button.

As to the question of diagnosis, the only symptoms present in all cases are pallor and vomiting, which may be present in any abdominal injury. The escape of gas, feces, or a considerable quantity of blood, indicates a perforating wound, and the latter implies a penetrating one. Blood in the stools or vomited matter is a valuable sign. I can not agree with a recent writer,* who says that when such signs are present it is too late to operate. Blood in the stools was present in Case II,

and not a few such cases, resulting in recovery, are on record.

Where any doubt exists, the enlargement and exploration of the wound seems to me to be the only satisfactory course. This can be done under cocaine anesthesia. In Case III it was applied to the wound of exit after extracting the bullet from beneath the skin; usually it is applied to the wound of entrance.

An important question to be settled is whether the stomach or intestines are perforated. It is possible to have a penetrating wound in which the bullet passes among but does not wound the intestines. Stimson has seen two such cases; in the War of the Rebellion nine such cases are recorded; and Oliver * reports three cases among fifty-eight. But in ninety-seven or ninety-eight per cent. of the cases, and probably more, a penetrating bullet wound is also perforating. The diagnosis of the latter condition should be made by the laparotomy undertaken for its treatment.

Senn has proposed the insufflation of hydrogen gas into the intestines by way of the rectum or stomach as an aid to diagnosis. This may be used in three ways: (1) After laparotomy, to determine the presence and situation of the perforations, so as to avoid the necessity for evisceration; (2) to determine the fact of perforation when penetration is proved and we have a more or less free opening into the peritoneal cavity; (3) to determine the presence of perforation as well as perforation. In each case the method seems to me objectionable because infection would inevitably be carried with the gas forced from within the intestine through an opening in its wall.

The amount of faecal extravasation in most cases, and in those detailed above, is not as great as one would suppose, but is ample to infect the peritoneum. In none of Oliver's fifty-eight cases, mentioned above, was there an appreciable amount of faecal extravasation, and, according to Martin and Hare, it only occurs in about twelve per cent. of cases. Though but little of the intestinal contents might be forced out by the gas, it is most undesirable to have any addition of infectious matter in the peritoneal cavity, even if it is soon to be removed.

The method is open to the most objection in (3), to the least in (1), in which any extravasation could be at once removed. When used in this way, it has the advantage of preventing the overlooking of any perforation. In short, as compared with gentle evisceration, I think it has no advantages in safety to the patient or security against overlooking perforations. If it were not for the fact that hydrogen gas is said to be rapidly absorbed, another objection to its use would be the direction of the bowel and the consequent difficulty in closing the abdominal wound, if not the more serious one of intestinal paroxysm from continued distention.

As to prognosis, many factors, liable to great variation, affect the result. The greater the number and the larger the size of the wounds, the worse the prognosis. The number is apt to be greater when the bullet passes in an oblique or transverse than in an antero-posterior direction. In all three of my cases the track of the bullet was oblique, but there was a large individual variation in the number of wounds.

Though in general the size of the opening varies directly with that of the bullet, there is a wide range here, for the bullet makes a much larger opening if, in its course, it passes through the side of a coil of intestine instead of through the middle, and in the former case the opening of entrance and that of exit may even be continuous.

The modern small-calibre, high-velocity bullets may produce various results in soft tissues depending upon whether they are soft-tipped or metal-clad. In the former case they tear large holes; in the latter, the wounds are small, clean, and like incised wounds.

Furthermore, the prognosis is affected by the condition of the stomach and bowels as to fullness or emptiness, for when they are empty faecal extravasation is less likely. This was seen in Cases II and III, but especially in Case II.

The part of the bowel wounded affects the prognosis, for a wound of the large intestine with its more solid contents is less likely to be followed by faecal extravasation than one of the small intestine. The stomach, although its contents may be very fluid, has thicker walls, so that the opening is more likely to be plugged by the protrusion into it of the mucous membrane.

The above circumstances affect prognosis by increasing or decreasing the amount of extravasation of septic matter and thus the degree of peritoneal infection. This is also influenced by the time between the injury and the operation. Thus, in a hundred and fifty-four laparotomies * for gunshot wounds the mortality varied from 52.7 per cent. when the operation was done five hours after the accident to 78.2 per cent. when done after twenty hours. After twelve hours the probabilities are strongly against recovery, and after twenty-four hours operation is practically useless. Morton † found a total mortality of 58.9 per cent. in a series of two hundred and thirty-four cases operated on in Europe and America. Statistics are liable to inaccuracy, however, owing to the successful cases being more generally reported than the unsuccessful ones. We may say, however, that when no operation is done in cases of bullet wound believed to be penetrating, the mortality has been fully ninety per cent. ‡

It is a curious fact in this connection that among the American forces in the Santiago campaign in the recent war it is said that no patient with a penetrating gunshot wound of the abdomen operated upon recovered,

* Sajous's Cyclopaedia, 1898 (Abdomen, Wounds of).
† Abdominal Section for Traumatism.
‡ See Wounds in War, W. F. Stevenson, London, 1897.
and that the only ones that recovered were not operated upon. But, in the first place, the number of those who recovered without operation, as well as of those unsuccessfully operated upon, was small; and, secondly, the facilities for operation were not of the best. Fuller details may explain this anomalous fact, though it may be said that more may recover without operation from penetrating wounds of the abdomen made by the modern jacketed bullet of small calibre and high velocity than would formerly have recovered from wounds made by softer bullets of large calibre. Hence better results may be expected from conservative military surgery than formerly.

But in prognosis we must not forget the personal equation. Different individuals react differently to similar peritoneal irritation. The proverb, "one man's meat is another man's poison," seems to apply here. We know that there is a great difference in this respect among various species of animals. Thus, a severe injury to the peritoneum of a cow is without gravity, while a horse is very susceptible to such injuries. Susceptibility seems to vary greatly among human beings and helps, perhaps, to account for some remarkable successes and for otherwise unaccountable failures. Case I was that of a man of fine physique and good habits; Cases II and III were the opposite. I do not mean to imply that differences in susceptibility are sufficient to account for differences in result, but that they may affect it slightly.

Hemorrhage from the wound of a solid viscus, or of a blood-vessel, even if it is small, renders the prognosis doubtful by increasing the shock.

It is difficult to give any definite figures of value in a given case as to the mortality of bullet wounds of the abdomen in general or of the intestines in particular, for there are so many variable factors. I have already given some general percentages above. Whereas before antiseptic surgery the mortality of perforating bullet wounds of the intestine was ninety per cent., it is said to have decreased to forty-three per cent. in cases operated on in the first twelve hours.* Considering the large total of thirty-three perforations in my three cases taken together, the mortality of only thirty-three per cent. seems a favorable one.

As to treatment, the necessity of operation is generally admitted: First, an enlargement and exploration of the wound to determine whether it is penetrating; then a laparotomy in such a position as to reach all parts of the peritoneal cavity, and especially those that lie in the track apparently taken by the bullet. The incision, as a rule, is best made in the middle line, through the rectus, an inch or so to one side of or through the semilunar line. If the diagnosis of perforation has not been made when the diagnosis of penetration is established the incision may be of moderate length at first; but as soon as the fact of perforation is known it is a mistake to confine ourselves to a small incision. It should be at least five or six inches long, for we can then treat the conditions present much more satisfactorily. The operation should also be done as soon as possible to give the best chance of success, but we may here be met by the question of shock as a contraindication to operation. If, however, the shock is due simply to the injury—and it may be severe after slight injuries, and vice versa—recovery is not long delayed under proper treatment. If the shock is due to hemorrhage, it is progressive and not diminishing, and we can not operate too soon.

On opening the abdomen in any case, the first thing to do is to check hemorrhage if it exists. It is scarcely necessary to say that perforations of the intestine should be closed by Lembert sutures. Interrupted sutures are more secure, but take more time, which is an important factor if the wounds are multiple.

Two rows of continuous suture are safer and more rapidly applied than a single row of interrupted sutures.

The liberal use of hot normal salt solution (1) to cleanse the surface after visible particles have been removed with a gauze pad, (2) to keep the exposed surfaces warm and moist, and (3) to combat shock is, in my judgment, of the greatest importance.

I do not believe in irrigation at all in a local process like a localized appendicitis, but the case is different here. We can not tell how far the infection has spread, for it is not coextensive with the spread of the visible extravasated particles, which may be altogether wanting when the invisible infection has spread very generally.

It is safer, therefore, to cleanse all parts thoroughly, and the other effects of the solution are also not to be lost sight of. I will only add that upon the question of drainage it is difficult to lay down hard-and-fast rules. If we are uncertain of the perfect closure of any perforation; if free serous exudation has begun from peritonitic irritation, due to infectious matter, or if more marked signs of peritonitis exist, most of us would prefer to drain. The ideal course is that without drainage, and there is a tendency in that direction in many abdominal operations; but in cases of perforating pistol-shot wounds safety is the paramount consideration.

A CLINICAL STUDY OF TWENTY-FOUR CASES OF
PARALYSIS AGITANS,
WITH REMARKS ON
THE TREATMENT OF THE DISEASE.

By JOSEPH COLLINS, M.D.,
PROFESSOR OF NEUROLOGY
IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL;
AND
L. J. J. MUSKENS, M.D.,
ASSISTANT IN THE CLINIC.

Paralysis agitans, or creeping palsy, has had but little added to its clinical delineation since the original description by James Parkinson in 1823. Despite the many careful investigations of the nervous system that have been made by the aid of modern methods, the nature of the disease is still unknown. Although classified as a functional nervous disease, pathological changes are almost invariably found in the central nervous system after death, especially if the disease has existed for a long time. The object of the present study is not to throw light on the pathology of paralysis agitans, but to consider its attributed and apparent causes, to estimate its relative frequency, to determine the initial symptoms and mode of onset, and to learn the factors that influence the course of the disease. The cases are taken from dispensary, hospital, and private practice, in about equal proportion. In order to estimate the relative frequency of paralysis agitans, we have taken the statistics of the clinic for several successive months, as it is impossible to approximate the number of nervous diseases that have been seen during the encounter of these twenty-four cases of paralysis agitans. In five hundred and thirty-six patients in the clinic, there were seven undoubted cases of paralysis agitans, and one doubtful case, making a percentage of 1.30. This is much higher than that given by many writers, such as Berger, who found a percentage of 0.62 in six thousand cases, although our figures are practically the same as those given by Charcot. The fact that the clinic is made up in considerable measure of patients sent there by physicians for consultation and advice may explain the relatively large percentage in our statistics. It is easy to understand that such statistics, therefore, have a restricted value in showing the frequency of paralysis agitans relative to all nervous diseases.

The accompanying table shows the relationship of age, nationality, and heredity to the occurrence of the disease:

The most striking feature in reference to nationality is the remarkable predominance of the Irish race. Very nearly one half of all the cases were of this people. When we consider that the constitution of the clinic is not conspicuously Irish, it will readily be seen that this preponderance is not to be explained by accident. It may be that the Irish, being a very emotional race, are more vulnerable to the attributed exciting causes of paralysis agitans: shock, anxiety, worry, depression, etc. It is not improbable, however, that it is in part explainable by the entirely different mode of life which the people of this race have when they take up their abode in this country, as no one has pointed out that the Irish are particularly afflicted with paralysis agitans at home. In other words, it would seem to be as much environmental as inherent. Another peculiar feature of the statistics concerning the nationality of the patients is the relative infrequency of the disease in Irish women, contrasted with the women of other nationalities. For instance, the Americans and Germans furnish an equal number of men and women. Many German and French writers maintain that there is very little relationship of sex to the occurrence of paralysis agitans. It will be seen that our statistics show that the occurrence of the disease is three men to one woman. Gowers gives the proportion in his experience as five men to three women.

Our statistics regarding the age at which the disease is most apt to show itself are in accord with those of most writers on the subject. The disease occurs most often in the fifth decade, and gradually diminishes until the eighth decade. Unlike many other writers, we have encountered two typical cases after the seventieth year. No patient under thirty years of age has been under treatment during the period of personal direction of the clinic, although previous to that time a typical case of paralysis agitans in a boy twenty-two years of age was under observation for a prolonged time. This case is not included in the statistics.

A fact brought out by our study that is not in entire
accord with the statements of other writers on this point is the influence of heredity. In no less than four cases was there a straightforward history of direct inheritance. In one case the father had paralysis agitans, while the mother and a maternal uncle died with some form of paralysis. In a second case the mother had a disease similar to that of the patient, the shaking being particularly marked when she was excited. In a third case, the father had an exactly similar disease for the last eight years of his life, and it is thought a paternal uncle was similarly afflicted; while in a fourth case, a woman, the father and a paternal aunt had exactly the same disease. Naturally, this information was obtained only from the patient or the descendants of the patients, and is therefore liable to serious errors. A very careful inquiry was made in every case on this point, with the above result, which is so at variance with the usual teaching on this subject that we are ourselves loath to accept it as absolute fact. A history of indirect heredity—that is, of manifestations of nervous or mental disease in the family—was found in sixteen per cent. of the cases. Upward of fifty per cent. of the cases gave neither direct nor indirect neuropathic history.

In regard to occupation, the statistics show that the patients were very evenly distributed among upholsterers, plasterers, gardeners, saddlers, engineers, printers, laborers, sailors, mill hands, promoters, journalists, clerks, merchants, and fancy workers. Neither the mentally harassed nor the physically overworked have a special liability to the occurrence of the disease. Workers out of doors develop the disease as frequently as indoor workers. The statistics further show that the disease is as likely to occur in one grade of society as in another. Of the six women, four were married, one was a widow, and one single; while of the eighteen men, sixteen were or had been married, and two were single.

Inquiry to determine the alleged causes of the disease did not result in obtaining satisfactory information. Only about thirty-five per cent. of all the patients were able to inform us of a distinct cause. The attributable causes were: 1. Shock attending the death of a beloved daughter. 2. Excessive and prolonged mental strain, incident to supporting a family. 3. Family trouble. 4. Constant exposure and becoming wet, incurred in occupation. 5. Contact of the hand with cold stone in winter, while employed in polishing marble. 6. An attack of grippe. 7. The sudden appearance of a strange black cat near her bed. 8. The discovery that an unmarried daughter was pregnant. 9. Being knocked down by a vehicle, but without consequent physical injury. 10. The discovery that all his savings had been lost. Thus it will be seen that the alleged causes were profoundly those that may be classified under the head of psychical or emotional trauma. Our experience in this respect corresponds with that of others, although, perhaps, the proportion in which an attributed cause was elicitable was somewhat greater than in those of other writers. It has frequently been stated that acute and chronic diseases of various kinds have a predisposing influence to the occurrence of paralysis agitans. This statement is corroborated to a slight extent by our study. Of the six women, four denied any previous disease. One had had a fungoid growth removed from the uterus shortly before the occurrence of paralysis agitans; one had had chronic diarrhea. A third patient had had yellow fever a great many years before the occurrence of the disease for which she came under our observation. Of the men, one gave a history of a blow on the head, after which he had been delirious for three months; but this had occurred so long before the manifestations of Parkinson's disease that it could not possibly have any influence. Another had had an attack of acute articular rheumatism before the manifestations of the disease; while a third, in whom the symptoms seemed to follow an attack of grippe, has already been mentioned. Two of the men had had yellow fever, eighteen years and forty years, respectively, previous to the manifestations of paralysis agitans. Only two of the twenty-four patients were hard drinkers or smokers, and in none was there a history of syphilis. As a matter of fact, the most striking feature of the personal history of all these patients was that they had lived temperate, wholesome lives, apparently devoid of undue strife or any uncommon burden. In a few cases the patients alleged that the onset of the disease was coincident with some annoying or exciting experience. For instance, one man was quite positive that the disease occurred immediately after leaving the witness box, where he had been subjected to a harassing cross-examination. Another patient dated the beginning of the tremor from the moment when he heard that all his savings had been lost, owing to the failure of a bank. But in both cases close inquiry revealed that muscular rigidity had antedated these experiences by a number of months. A third patient averred that the tremor developed while he was lying in bed convalescing from an operation for inguinal hernia, but investigation showed that the surgeon had diagnosed agitated paralysis agitans on the man's admission to the hospital.

This brief review of the etiology of paralysis agitans shows that the most important factors are age, sex, nationality, morality, violent emotions, especially depression, direct and indirect heredity, and infectious diseases. Apart from the peculiarities of our own statistics relative to these factors, and which have already been mentioned, the only point worthy of note is that traumatism was not an alleged or exciting cause in a single instance.

Symptoms.—The disease usually develops in a most insidious way, although it may come on with considerable abruptness. The first complaint may be of profound and unattributable weariness, usually of one upper extremity. This may or may not be associated with trembling of the extremity, but the latter is sure to follow. With the feeling of weight, fatigue, and unworldliness of
the extremity, a peculiar form of muscular rigidity develops. This rigidity is more apparent to the patient than it is to the physician on passive movement. Although this rigidity develops first in one extremity, it soon passes insidiously to the others, and eventually is manifest in every part of the body. It is responsible for the peculiar, immobile, expressionless countenance of the patient’s face, for the bowed condition of his body, and for the slight flexion in all the articulations of the long bone. Moreover, the contraction which is at the bottom of the spasticity conditions the patient’s gait, with its short, shuffling steps and tendency to run, called festination: inclination to fall forward (propulsion), as well as the tendency to fall backward (retropulsion), especially if the patient starts to move in that direction, and the inclination to fall sidewise (lateropulsion). It is responsible likewise for the high-pitched, unmodulated, monotonous vocalization and the fixed manner of speech. The tremor, which is considered an essential feature of the disease, may never develop; but usually it shows itself a few weeks or months after the rigidity and fatigue in one hand, oftentimes in the left. Occasionally it precedes the occurrence of rigidity of the muscles. It gradually creeps up to the shoulder, accompanied by a peculiar subjective sensation of unrest, and passes across to manifest itself in the upper extremity of the opposite side. Later it shows itself in the lower extremities, and finally, as a rule (although this is contrary to the usual statement), in the cephalic extremity. It has three characteristics: First, its location, usually in the hands, which are already brought into a pencil-holding position by the muscular rigidity. It oftentimes causes a forward and backward movement of the thumb and the index finger comparable to those of rolling a pill, often called a pill-rolling movement. Second, its rapidity, from five to six a second, therefore standing midway between the slow tremors and the rapid or fine tremors. Third, it continues while the patient and his extremities are supported and at rest. Although it usually lessens in intensity when the patient attempts and performs voluntary movement, it oftentimes does not do so, and may indeed become slightly exaggerated. Occasionally it stops without apparent cause, but reappears without attributable exciting factors. It is increased by all forms of psychic excitation and by physical indulgence. It may involve all the extremities, and usually does so before the patient passes into the terminal stage, wherein the rigidity and immobility again have sway, as they often do in the beginning. In addition to these symptoms, which are looked upon as the leading features, there are many associated phenomena, all of them apparently perversions of the sympathetic nervous system. There are subjective sensations of heat, accompanied by local flushings, especially of the face and chest, by local and general elevation of temperature; attacks of sialorrhoea, diarrhoea, and outbreaks of sweat, which may or may not coincide with the flushings just spoken of; with sluggishness of the pupils on exposure to light; and profound myasthenia, both paroxysmal and continuous. The sensory sphere is usually entirely spared. The cutaneous and deep-seated reflexes are normal, unless the phenomena of the latter are prevented by the rigidity. The bowels and the bladder preserve their function, save in the manifestation of hurried action of the sphincters, and the digestive organs remain in fairly good working order. The patient is non-emotional, and exhibits a degree of contentment which is strikingly at variance with that which one would expect to find in a normal man or woman who had been deprived of their capacity to enjoy life or earn their daily bread, and who have probably been apprised of the eventual outcome of their disease. Nevertheless, there is no dementia; at least, not until the disease is nearly at its end. Aside from the subjective sensations of fatigue, oppressive warmth, fullness in the head, and difficulty of prehension and locomotion, the patient’s most frequent complaint is of sleeplessness and inability to get refreshing rest.

The course of the disease is uniformly progressive. In this it is strikingly in contrast with a disease which tradition maintained, and some still teach is frequently mistaken for paralysis agitans—viz., disseminated insular sclerosis, which is almost invariably progressive and retrogressive. The disease lasts from five to thirty years. As a rule, the patients pass into a bedridden and asthenic condition, which makes different parts of their body vulnerable to infections, such as tuberculosis and pneumonia, and they die from these or other intercurrent disease.

Despite the fact that the symptoms of paralysis agitans are very characteristic and constant in their occurrence, the early clinical features of the disease are really quite variable. For instance, the time that elapses between the occurrence of a symptom that will be sufficient to direct the physician’s attention to the real nature of the disease and the recognition of the serious nature of the complaint by the patient, is very variable. This is well illustrated by a few examples. One man observed that the left index finger was tremulous when he walked in the street. Eight years later he complained of cramps in the calf and instep of the left foot. Six months later still there was very characteristic agitation of the entire left upper extremity; while in the course of two years from this time all the extremities were affected, and the patient was in an advanced stage of the disease. The facies, the attitude, the tendency to propulsion, the speech, the drooling, etc., were all most typical of Parkinson’s disease. In this instance the time between the initial symptom and the occurrence of characteristic symptoms was extremely protracted. Another point worthy of note is that the tremulousness preceded the muscular rigidity, this formula being usually reversed. Another patient came to the clinic on account of peculiar sensations in the head—a fullness and feeling of distention. He also complained of heaviness and weak-
ness of the extremities. The slight, rather jerky tremor which was noted in the right hand he made light of, as it did not bother him. The facies, speech, vasomotor disturbances, and slight rigidity of the extremities were sufficient to warrant the diagnosis. Twelve months later we saw him again, when he had typical tremor and rigidity of all four extremities. Another patient averts that the initial symptom was a tendency to stagger, as if he was drunk, which preceded by six months an agitation of the right hand first noticed on writing. An interesting feature of this case was that he was one of the very few that showed any considerable mental depression. Another patient complained of stiffness in all the joints for upward of four years before any tremor showed itself. One woman assured us that the initial symptom in her case was pain in the right shoulder, which was followed in five months with pain in the right hand. Before the year was passed the right hand was tremulous in a characteristic fashion. Some time after that she complained of pain in the left shoulder, and later in the left hand. Then this extremity became tremulous. Thus the pain and tremor extended to involve the four extremities. Another woman said that she had had pain in the right thumb almost steadily for three years without any other symptom save a variable amount of acroparæsthesia. At the end of this time tremor began in the index finger and thumb of the right hand, the movements being of the "pill-rolling" character. Another woman says that the initial symptom was inability to move around as agilely as formerly, especially in the morning. After this condition had lasted for a year or more she remarked a tremor in the right hand. Another woman states that the early symptoms in her case were referable entirely to the stomach, a sensation of fullness and agitation in the stomach, associated with flushings of the face and attacks of unaccountable perspiration. Two of the male patients stated that both hands began to shake simultaneously, and that this agitation was the initial symptom. In all the other cases the tremor was unilateral in its onset.

Recently, Dr. Purves Stewart has described what he believes to be a new and early symptom in paralysis agitans. It consists in a peculiar affection of the toes, which causes them to become spontaneously strongly flexed and curled up under the sole in a cramp-like fashion when the patient is walking. We have made careful inquiry and examination in ten of our twenty-four patients now under observation, and have found nothing approximating this, save perhaps in one case. In our experience it is neither an early symptom nor a symptom at all, except as cramps in various parts of the body are of occasional occurrence. Two of our patients complained of cramp in the foot, which, however, was as liable to occur while the patient was lying down as when moving about. Three patients suffered considerably from cramps in the legs. Considering, therefore, that involuntary, painful contractions of various muscles were noted in upward of twenty-five per cent. of the cases, it would seem more legitimate to call this a "new symptom in paralysis agitans" than "curling" of the toes.

Our statistics show that the type of the disease was preponderantly diplegic, which, it may be said in passing, is at variance with the statement of most writers, who say that the symptoms of the disease in most cases are hemiplegic in distribution. Thirteen of the cases were diplegic, three hemiplegic, and two tetraplegic. In three of the remaining cases the symptoms were more pronounced on the left side than on the right. This, however, does not place them in the hemiplegic category. Only two of the cases were of the monoplegic type. In one case the lower jaw was distinctly affected. Of the twenty-four cases, one only was devoid of tremor. This was a most typical case of Parkinson's disease in a laborer sixty-one years of age. At the present writing his disease has lasted upward of five years, and there is no evidence of tremor. No general statement can be made concerning the earliest symptom in every case of paralysis agitans. As we have pointed out, this is variable with each case. Although tremulousness is the symptom for which the patient first seeks relief, careful inquiry will usually show that rigidity, amyosthenia, and diminished agility have antedated the tremor for a longer or shorter time.

Study of our cases relative to the nature and the rhythm of the tremor goes to corroborate the customary teaching. The rate was in all cases from three to six per second. The amplitude of the tremor increased with the progress of the disease. In three cases the tremor was distinctly intentional—that is, it was increased by purposeful movements. In some advanced stages it was noted that voluntary action had decidedly a quieting influence upon the tremor. In nearly every case the tremor was increased by excitement, reproof, mental agitation, etc. In two cases only was it noted that physical agitation had a soothing influence upon the tremor. Many German writers state that the head very rarely participates in the tremor, while Charcot taught that this was the exception, not the rule. This was inquired into in all of our cases, and in five there was distinct tremor of the cephalic extremity.

As to the influence of sleep, in nine cases of which definite information could be obtained, the tremor always stopped during sleep. One man was very positive that toward morning he was awakened by a spontaneous fit of shaking.

In eleven cases the state of muscular tonicity was measured with Dr. Muskens's tonometer, some of them repeatedly. Without entering into details of this method here, it can be stated that in three cases of the hemiplegic type in which there was no tremor nor stiffness of the opposite leg, the tonometer showed a distinct in-

---

* Lancet, November 12, 1898.
crease of tone. In fact, in only two cases was there found normal tone of the legs. It may therefore be concluded that increased tone is a very early symptom, and probably always precedes the tremor and rigidity.

The respiration was studied in eleven cases. In four cases it was regular and deep, without particular change. In four cases it was superficial and of increased frequency, twenty-one to twenty-four a minute. In three of these last cases the expiration was irregular and jerky, while the inspiration was regular and harmonious. In one case it was distinctly noted that the jerkingness of the expiration coincided with the tremulous movement of the arm, but in the other two cases this was not so.

In fifteen cases special inquiry was made concerning the existence of propulsion, retropropulsion, and lateropulsion. In seven cases all knowledge of its existence was absolutely denied. In five of the remaining eight cases the patients complained of a tendency to fall forward. In four patients there was at the same time some retropropulsion and lateropulsion. In two patients of the hemiplegic type lateropulsion was present, the tendency being to fall toward the diseased side.

In sixteen cases inquiry was made concerning the state of the stomach and bowels. Eight patients complained of obstinate constipation, one patient had chronic diarrhea, another had occasional attacks of diarrhea, while the remaining seven made no complaint of their gastro-intestinal functions.

Abnormal heat sensations were complained of in five cases out of fifteen, in which it was noted that inquiry had been made in regard to this condition. The hot flashes were usually of the face, but not infrequently also manifest in the side showing the tremor. In four cases perspiration was a very disagreeable symptom. As a rule, it occurred rather late in the disease. In one instance alone was it an initial symptom. Drooling was a very distressing symptom in two cases.

The mental condition of the patients was noted in nineteen cases. Eleven were cheerful, hopeful, of good disposition, and easy to get along with. This, taken in connection with the fact that some of them were inmates of a charity hospital whose environment is not particularly contributable to the mildest degree of euphoria, means a great deal. In none of our patients was there any perceptible degree of dementia. Four of the patients were at times considerably depressed; but of these, one was trying to carry on a business, and another was subjected to considerable harassment in a law court.

Treatment.—Unfortunately, no medicament has yet been discovered that has any influence in shaping the course or changing the outcome of this disease. Beginners in the art of therapy should keep this in mind, and thus spare themselves the trouble of attempting a cure by any of the drugs—and their name is legion—that have been recommended during the last half century. Energy of this kind and zeal for experimentation may be legitimately expended, perhaps, in trials with new drugs and other health-restoring measures. But it should not be forgotten that one is not always justified in elevating the hopes of the patient for recovery so high or so often that when the promises are not fulfilled their confidence is so completely shattered that only harm results. Despite this depressing estimate of the value of drug medication in the treatment of paralysis agitans, much can be done to alleviate the symptoms, to prolong the patient's life, and to make him more comfortable. As in all other nervous diseases, the dietetic and disciplinary treatment are of the greatest importance. Their value is very conspicuously seen in patients who early in the course of the disease are obliged to seek the shelter of a hospital. Although they are apparently and really not very ill, as wage earners they are incapacitated. The regular mode of life, and all that is implied by hospitalization, is conducive to avoidance of wear and tear, and such patients continue year after year without any material change except slight increase of rigidity, tremor, and the other cardinal symptoms. The first indication, then, is for the arrangement of an uneventful life, free from care, strife, excitement, and sordidity, in a congenial environment and healthful climate. As a rule, a cool climate is far more grateful to these patients than a hot one. Residence in the country or in the suburbs, where a maximum of fresh air, sunlight, and sleep are to be had, with a minimum of demand on the mind and the body, meets the requirements, providing the vital force of the patient is not put to a severe test in withstanding extremes of temperature.

The diet should be of a simple, nourishing, strengthening kind, and close attention must be given to the functions of digestion and of absorption, so that the bodily weight may be kept at the level which was normal in health. The comfort of the patient can be materially added to by regulation of the bowels and other eliminative avenues. It is absolutely necessary that the patient has the personal care of an attendant or one of the family. Disastrous accidents have not infrequently followed neglect of this precaution. The customary measures for the maintenance of general muscular tone and nutrition, so serviceable in many functional and organic nervous diseases, such as the application of water and electricity, the use of massage and gymnastics, are not so appropriate in this disease as they are in many others. Nevertheless, the use of lukewarm baths, of from twenty minutes to half an hour's duration, are oftentimes very soothing to the patient, and have a tendency to make the muscular rigidity less dominant. Moreover, they contribute to a moderate feeling of well-being, and assist toward the realization of refreshing rest for which the patient generally clamors. In patients under forty years of age, the application of water from 90° to 75° F. from the hand of an attendant, followed and accompanied by friction, is sometimes serviceable in combating the distressing attacks of local and general heat of which the patient com-
plans. This measure can be utilized daily with patients who react well after it. Reaction may be facilitated by having the patient wrapped in a hot blanket previous to the ablution, by having him stand in hot water during the bath, and by light massage and external heat following it. Massage, applied as stroking and light kneading, fulfills practically the same purpose and is utilized for the same ends. Papotement or percussion should be avoided. It tends to lessen the spasticity, to improve the general nutrition, and to increase the patient’s capacity for rest. Swedish gymnastics has been warmly recommended by some writers, but we have never seen anything, but detriment attend its use. The same may be said of suspension, which has been plentifully tried, and of nerve stretching. They are mentioned only to be advised against. A few years ago Charcot pronounced the fact that many of his patients with paralysis agitans were more comfortable during and after a short ride in a jolting vehicle. Assuming that the jarring and vibrations had a soothing effect on the nerve centres from which arise the tremor and rigidity, this clinician had a chair so constructed that the patient or an attendant could, by pushing a pair of upright handles backward and forward, communicate vibration to the entire body. Such a chair was in use for many months in my clinic, but nowadays it subserves only a single purpose, a seat. Its uselessness is no greater than that of other vibratory apparatuses, such as the one for the head, that have been constructed with a similar end in view. Electricity has practically no place in the therapeutics of paralysis agitans, excepting so far as it is a potent agency for suggestion. One of the most striking results of treatment in paralysis agitans is the temporary amelioration of all the symptoms on undertaking any new form of treatment. We have now under observation a man in the advanced stage of the disease who some years ago maintained that he was materially improved by some mechanical treatment given to him by another physician. On inquiry, it was found that the “treatment” consisted of taking a few tracings of the tremor. Oppenheim states that he has seen considerable benefit follow the electric bath, and especially the application of the dipolar faradate current, but it is not improbable that the bath alone would have been accompanied by quite as much improvement.

The drugs that are in use for paralysis agitans, and from which some benefit in dissipating symptoms and fulfilling pointed indications may be expected, are hyoscynamus and duboisine, Indian hemp, opium, hematogenous agencies, such as arsenic and iron, and occasionally gelsemium and veratrum viride. Of these, the most important by far are the two first mentioned. Given hypodermically, which is the preferable way when possible, or by the mouth, they promptly mitigate the severity of the tremor, and have a pronounced tendency to relax the muscular rigidity. They are both powerful toxic agencies, and must therefore be given with care. Hyoscyamus (hyoscine hydrobromide, one one hundred and twenty to one eightieth of a grain) is said to have more advocates than duboisine, but, personally, we much prefer the latter. Its administration is not so apt to be attended by disagreeable symptoms, while the effects are coequal. The sulphate of duboisine should be given in from one one hundredth to one sixtieth of a grain, two or three times daily. On the accession of vertigo, cephalic paresis, disturbance of vision, nausea, dryness of the mouth and tongue, it should be stopped at once. In many instances the administration of either of these drugs is followed by almost complete cessation of the tremor for a shorter or longer time, but usually for several days. Unfortunately, they apparently have slight effect in mitigating sleeplessness, amyosthenia, and the feeling of unrepose that so many patients complain of. When these become too burdensome for the patient to bear unaided, opium or its alkaloids, preferably morphine, must be given, and especially to cause rest and sleep in advanced cases. Earlier in the disease reliance can be placed on the less baneful sleep producers, such as sulphonial, trional, paraldehyde, etc., given in the same way as they are for idiopathic insomnia. The salts of salicylic acid, particularly those of sodium and potassium, have been widely recommended, especially during the last ten years, probably suggested by the patient’s complaint of rheumatic pain and by the occurrence of other more characteristic phenomena of rheumatism. After thorough trial, we are convinced that such medication is quite useless. Considering the profound degree of depression in neuromuscular tone which patients with this disease have, it seems incredible that the bromides have ever been recommended or given, but, unfortunately, they have been. They are powerful agencies for harm, and the thought of their administration should never be harbored. In some instances, especially in those cases that are not benefited temporarily by duboisine or hyoscynamus, some mitigation of the tremor and rigidity may be obtained by the administration of gelsemium or veratrum viride in from three- to five-drachm doses, three times a day. These drugs have served us more satisfactorily as symptom medicines than Indian hemp, which has the recommendation of Gowers, and which has been widely used.

Suture of the Axillary Artery.—At the French Society of Biology M. Ricard (Indépendance médicale, May 31st) recently presented a patient upon whom an operation had been performed eighteen months previously for an adenopithelioïsm. In the course of a second operation the recurrent tumor was resected, but the artery, being surrounded by infected glands, was accidentally opened laterally in the course of the dissection. A longitudinal suture of the artery was forthwith made and the fact of the blood passing by the sutured artery was evident to the sight. The radial pulse was at once re-established and had remained permanent, which showed that the suture had held and that no clot had obstructed the vessel.
THE
ETIOLOGY OF TEXAS CATTLE FEVER,
WITH SPECIAL REFERENCE
TO RECENT HYPOTHESES CONCERNING THE
TRANSMISSION OF MALARIA.*

BY THEOBALD SMITH, M.D.,
GEORGE BARYAN PROFESSOR OF COMPARATIVE PATHOLOGY
IN THE MEDICAL DEPARTMENT OF HARVARD UNIVERSITY;
PATHOLOGIST TO THE STATE BOARD OF HEALTH OF MASSACHUSETTS.

The studies upon human and animal diseases carried on recently by Koch in the heart of Africa, and his enunciation of an hypothesis concerning the transmission of malaria by stinging insects, more particularly by mosquitoes, have drawn attention to the etiology of Texas cattle fever, upon which his hypothesis was based. Our studies on Texas fever have been so fully recorded that the only excuse I have in accepting the invitation of your president to bring out once again the salient facts in the etiology of this most interesting disease is the moral support which it may tend to give to the inoculation hypothesis of malaria, in which I have been a firm believer for several years, until it can either be disproved or satisfactorily demonstrated to be true.

It was known for a good many years by farmers and agriculturists of the United States that healthy cattle driven north beyond a certain line during the warm season of the year would infect pastures with a virus highly fatal to the native cattle grazing on them.

When in 1868 the early slow process of driving cattle afoot was abandoned, and the steamboat and the railroad were substituted, this peculiar disease was disseminated over a wide territory, even reaching this city. It was also known that cattle driven south from the northern side of this line contracted the same disease. The investigations of Dr. D. E. Salmon during the years 1880-'84 defined more accurately this line, and showed the existence of a large permanently infected territory, including most of the Southern States. At present the National Government issues annually rules and regulations governing the movement of the cattle from this enzootic territory, so as to protect the live-stock interests of the North. But even now the rules are sometimes broken, and in 1897 this disease appeared in a number of cows about Boston. The virus had been dropped in the Albany stock yards, and from there taken to those near Boston. The line, as drawn at present by the Department of Agriculture, meanders across the country between the twenty-ninth and forty-second parallels of latitude.

The importance of knowing something of the mysterious agencies of this disease led the government and some of the States to induce a number of persons to investigate it. Beginning with 1868, various reports have been issued, the most satisfactory of these being one by R. C. Stiles on investigations made in this city in 1868 for the then Metropolitan Board of Health. Its only disfigurement is the part added by Ernst Hallier, of Jena, on the etiology, which serves well to illustrate the vagaries of pseudo-science. Of the other reports dealing with the etiology, the less is said the better. They can be resurrected by any one so desiring, by consulting the references in our full report.

In 1888 I was first introduced to this subject by examining portions of the organs of animals which had succumbed to it in Maryland and Virginia. These were brought to the laboratory at Washington on ice. At this time the only report which pretended to make any detailed statements concerning the lesions produced by Texas fever was the one by R. C. Stiles. It was therefore necessary to study the subject from the bottom to get some data on which to found the etiological work. From the pieces examined in the summer of 1888 I became convinced that a corpuscle-destroying parasite was at work. Laveran's discovery and subsequent researches by Italian writers, more particularly Golgi, had paved the way for this assumption. The material was not in any satisfactory condition for studies of the blood, and this part of the work was postponed until the blood of a living animal could be examined. In the meantime appeared Babés's work on the hemoglobinuria of cattle in Roumanian.* Babés found in this disease a coccus within the red corpuscles, which he cultivated, though with difficulty, and passed through several rabbits. Subsequent events showed that he saw the true parasite, but went astray in assuming that it was a bacterium, and in cultivating some other organism, possibly that of rabbit septicaemia. He regarded the drinking troughs as disseminators of the disease. Since his first communication Babés has gradually converted his diplococcus into a protozoan parasite, and has reported the presence of ticks upon Roumanian cattle. Through the efforts of Dr. Salmon, chief of the Bureau of Animal Industry, my wish to have diseased animals within easy reach of the laboratory was carried out in the summer of 1889, and the very first cases revealed the intraglobular parasite.† It was only necessary now to interpret certain peculiar appearances of the blood-corpuscles, due to the extreme anaemia,‡ which might have been taken for stages in the life history of the parasite, and we had a ready means of diagnosis. The microscope and Thoma's blood-corpuscle counter, aided by the clinical thermometer, were thereafter the chief

* Read before the New York Academy of Medicine, April 6, 1899.
‡ Transactions of the Association of American Physicians for 1891.
means of recognizing the disease. The work accomplished in the summer of 1889 furnished us with certain data concerning the pathology of Texas fever and the micro-organism to which I shall very briefly allude before taking up the mechanism of its transmission.

The acute type of the disease begins with a high fever, reaching not infrequently 107° and 108° F. The animal may succumb after three or four days of fever or after a week. In rare cases recovery takes place. During the fever only several per cent. of the red corpuscles in the peripheral circulation contain parasites. There is, however, very rapid destruction going on at the average rate of half a million of red corpuscles per cubic millimetre a day, leading in many cases to a fall from six to 1.5 million in a week. The lesions vary from case to case, depending on the duration of the disease. When the animal succumbs in the first week, the spleen is found enormously engorged, the pulp partly disintegrated. The liver is greatly enlarged, of a yellowish or saffron hue, and the bile is of the consistence of chewed grass. In sections of the fresh organ a beautiful network of bile canaliculi injected with a semisolid bile may be seen. In later stages this has disappeared, and the central portion of the lobule is now in a state of coagulation necrosis. The kidneys are enlarged, edematous, suffused with the coloring matter of blood, and frequently the fatty tissue around them is in a state of hemorrhagic edema. The bladder is full of wine-red or even blackish urine. Red corpuscles are not present in it. Hemorrhagic spots are quite common in the heart muscle, especially under the endocardium. If these various organs are examined in smear preparations, a very large number of infected corpuscles may be found in the spleen, liver, kidney, heart muscle, and plexuses of the brain. In the kidney they are largely free and resemble cocci of varying dimensions. In sections the infected corpuscles are found in the form of capillary plugs, traceable in thick sections for some distance. The parasite in the acute disease is thus largely restricted to the capillaries of the internal organs. The heart muscle has generally furnished me with the most abundant and characteristic parasites.

Starting from this acute type we may encounter all gradations down to the mildest manifestations, recognizable only by the study of the red corpuscles and the blood count. Superficial examination may even miss the rare parasites in the peripheral circulation, but in all cases the marked fall in the number of red corpuscles and, in default of an enumeration, the characteristic basophilic substance in the red cells of oligocytthermia, staining diffusely or in granules with Löffler's methylene blue, may furnish a satisfactory diagnosis. Any detailed description of the morphology of the parasite would be out of place in this paper, the more so as nothing new has been added to our knowledge since 1893. Certain statements made by Koch concerning the earlier stages are easily harmonized with existing information. It is sufficient to state that the reproductive stage of the micro-organism has not been made out. There are several points, however, to which I should like to allude briefly. The earliest stage of intraglomerular life I believe to be a motile, rodlike form of very small dimensions, whose movements within the corpuscle from one side to the other can be followed in the fresh blood.

It is not brought out by staining. In further development of the organism, it is highly probable that there are two different modes of reproduction, similar to those first suggested by R. Pfeiffer for Coccidium oviforme, and recently made out by the combined labors of MacCallum, Simond, Siedlecki, Léger, and others for other sporozoa—namely, a reproductive process adapted for rapid multiplication within the host and one for an environment different from that of the host. This theory harmonizes many puzzling phenomena, among them the very rapid multiplication of the parasite in the susceptible animals leading to acute disease and the slow, but continuous, reproduction in the immune. None of the many animals other than cattle inoculated with infectious blood were found susceptible. The work was thereby made much more laborious and expensive.

That ticks carry the disease was suspected for many years. In 1868 Mr. John Gamgee, imported from England to study this plague for the government, wrote: "The tick theory has gained quite a renown during the past summer, but a little thought should have satisfied any one of the absurdity of the idea." When the disease was first produced near Washington by the importation of healthy North Carolina cattle, F. L. Kilborne, then superintendent of the government farm where the field experiments were conducted and in charge of the experimental animals, suggested two experiments—the infection of fields with ticks alone and the removal of ticks from Southern cattle to be penned with the natives. These were carried out and repeated during three successive seasons. They showed quite satisfactorily that the popular belief that the tick is necessary to the infection of pastures was well founded. They naturally led at first to the assumption that pastures are infected by ticks drawing the parasite with the blood, and that the native animals are infected by grazing over the infected soil, somewhat analogous to Manson's theory of the relation of mosquitoes to malaria. In order that we may understand the reasons that led to a wholly different result, a brief review of the life history of the tick is necessary. While studying this ectoparasite in 1889 I noticed that the female would lay her eggs in captivity. This fact enabled us to fill in the gaps in the life history not easily observed in the field, and Cooper Curtice,*

* Journal of Comparative Medicine and Veterinary Archives, 1891 and 1892.
then helminthologist of the Department of Agriculture, studied more in detail the development of the tick by placing the young upon a heifer and watching their growth. The young six-legged arachnid, after emerging from the egg, fails to develop until placed on its special host. I have kept individuals from December to May in culture dishes without noticing any change beyond a gradual destruction due to the artificial environment. When placed on cattle, their growth begins at once, and in about a week the first moult takes place, when the animal appears provided with another pair of legs. In another week a second moult introduces the sexually mature period. Fertilization then takes place, and the female begins to swell up with the growth of eggs and the large amount of imbibed blood. After about three weeks of parasitic existence the ripe female falls to the ground, deposits one to two thousand eggs, and dies. The period of development of the embryos on the soil varies within very wide limits, depending entirely on the temperature. Fifteen days is the shortest period I have observed. After emerging from the egg, the young at once seek to attack themselves to their host and begin the life cycle anew. The age of one generation, embracing the period of incubation of the ovum and the parasitic life, averages from forty to seventy days. It will be seen from this sketch that the cattle tick is exclusively parasitic in its habits, and that it does not pass from one host to another, but completes its life upon one animal.

In the second summer season, after the pathology and parasitology of the disease and the life history of the tick had been fairly apprehended, the sudden simultaneous appearance of high fever in the animals exposed in infected fields, and the new brood of ticks upon them, forced upon me a flash the conviction that we were here in the presence of a wholly new fact in the domain of aetiology. Everything pointed to the young tick as introducing the disease by inoculation, in spite of the newness and apparent awkwardness, as it were, of this hypothesis. Especially strong testimony in its favor was the long period of incubation. The susceptible animals penned with Southern animals or in fields infected with ticks remained absolutely well for five weeks or longer after the earliest date of field infection; then with a bound the temperature rose, and in a week the majority were dead. I ransacked the older records to obtain more evidence upon the period of incubation, but the few instances recorded confirmed our field observations. This period, it should be borne in mind, dates from the infection of the pasture and not from the date of exposure of cattle on it. The tick embryos continue their development whether cattle are present or not. After the young brood has appeared, a week or even less time suffices for the outbreak of disease. This hypothesis, that the progeny of the infected tick produces the disease, left me in doubt for a time concerning the aetiological relation of the blood parasite. Could not a poison be introduced by the young tick into the blood of cattle which destroyed certain inhibitory mechanisms, and thereby favored the multiplication of an ordinary blood parasite? This doubt was nurtured by the occasional discovery of very minute refringent bodies of varying outline within red corpuscles of susceptible but healthy native cattle. Two lines of experiments were carried out to meet these new developments: First, the rearing of young ticks artificially in the laboratory and the infection of cattle with them; second, the transmission of the disease from one animal to another by the injection of infected blood without the inter-mediation of the tick. Both were successful. The first demonstrated the infectious character of the young tick, the second that the blood parasite, and not any poison introduced by the tick, is the real cause of the lesions. The disease produced directly with young ticks appeared to be somewhat less fatal than the natural exposure. This may be due to certain interferences with Nature’s processes, such as the removal of female ticks before they are quite ready to drop, and the artificial incubation of the ovum.

This disease may now be produced by any one, in midsummer, by sending to the permanently infected territory for ripe female ticks and incubating the eggs laid in confinement. As the disease does not spread from an inclosure, and as the ectoparasite is destroyed by frost, any danger to live stock is out of the question, if a little care is exercised. Any spot of ground once infected may remain so during the warm season, owing to the persistent vitality of the young tick until frost comes. The disease may in this way be exploited, if sufficient means are at hand, in the interest of a broader aetiology and pathology than that fostered for the promotion of agriculture by our national government. I would warn any one, however, against the danger of drawing conclusions from the study of too few cases. The wide range of pathological changes in the blood and tissues and the variable degree of blood infection should always be borne clearly in mind. The life of the blood parasite in the tick has not yet been elucidated. It seems most in harmony with biological science to assume that the ova become infected, and that in the young tick certain organs analogous to salivary glands, connected with the operation of drawing blood, discharge the parasite into the blood of the host.

Since the aetiology of the American disease has been cleared up the same malady has been found to exist in Finland, Roumania, Italy, Australia, South Africa, and German East Africa. It will probably be found in other similarly situated countries whenever a migration of cattle shall have taken place which will tend to mingle immune and susceptible animals. It is strange that so little attention has hitherto been given by others to the transmission of the disease. Koch showed his unusual sagacity in seizing upon this one feature of the aetiology and investigating it to satisfy
himself. Undoubtedly the fairy-story element about the transmission of the disease by the progeny of the infected ectoparasite, as Koch himself expresses it, led the various observers to take the position of John Gamgee, that "a little thought should have satisfied any one of the absurdity of the idea."

There are several phases of this remarkable disease which have a very important bearing upon etiological studies of malaria; to these I wish to allude briefly before concluding. The persistence of the parasite of Texas fever in the blood after recovery, and for years after the immune Southern animal has left the enzootic territory, shows that a kind of symbiosis has been established between host and parasite. This symbiosis begins early in the life of the Southern cattle with perhaps several mild attacks of fever, and thereafter, though they remain well, they are nevertheless the carriers of a fatal infection for the non-immune Northern cattle. Their blood produces the acute type of Texas fever when injected under the skin. This fact I regard as next in importance to the demonstration of the transmission of infection by the offspring of ectoparasites, because it proves that the blood parasite of Texas fever may exist for some time independent of the tick. Whether, under such conditions, in the course of time it may lose the power of existing in the body of the cattle tick, and thereby become non-transmissible excepting by direct inoculation, is quite within the domain of probability. Another important fact determined by these investigations is the acquisition of immunity toward protozoan diseases. This was so thoroughly demonstrated that I need not dwell on it here. A high degree of immunity is not so easily acquired, however, as Koch's recent statements would lead us to suppose. I am inclined to believe, after a careful study of his experiment, that he was dealing with animals already endowed with considerable resistance. We know from the various researches on bacterial immunity that a partly immune animal becomes highly resistant after but little treatment. A very interesting clinical confirmation of the capacity of animals toward the acquisition of immunity is provided for us by the course of the disease itself. When animals are infected in the early months of summer the disease assumes the acute form, with high continued fever and rapid destruction of corpuscles. If the animal passes the first week alive it may recover. The temperature then falls and a rapid reproduction of red corpuscles takes place. Then there may be one or two very brief periods of high temperature with evident loss of red corpuscles and the transient appearance of parasites in the blood. Three to five weeks after the first attack there is ushered in a modified or mild type of the disease, not suggested by any outward signs of disease, but recognizable by a higher evening temperature, by persistent anaemia, and by the appearance in the peripheral circulation of large numbers of infected corpuscles. The blood parasite in this mild type or relapse appears in a form not encountered in the first acute attack. It is very small coccus-like, and situated on the periphery of the red corpuscle. These bodies, associated with very rare forms of the large pyriform bodies, may persist for four or five weeks, or until the colder weather comes. Then their disappearance ushers in the period of normal temperature and rapid rise in the number of red corpuscles. This type of fever is common in the fall, the acute stage preceding it being short and frequently not noticed. I have interpreted the peculiar features of this mild type or relapse as a resultant of partial, acquired immunity, in virtue of which the development of the blood parasite is greatly retarded, and perhaps modified, and the infected corpuscle may circulate a longer time before it becomes caught as a foreign body in the capillaries of the internal organs.

These two facts, the persistence of the blood parasite and the acquisition of immunity, I have used in building up a working hypothesis in studying the dissemination of tertian malaria in Massachusetts under the direction of the State Board of Health since 1896. This hypothesis assumes first of all the introduction of the malarial parasite into a region in the body of human beings. If the conditions are favorable—i.e., if the infected individuals live near standing water to which mosquitoes may speedily repair and lay their eggs, and if individuals are readily accessible to the young brood for infection—the disease is likely to take root and become endemic. The blood parasite is protected over winter in the body of the infected human being. The larger the number of these, the more difficult the eradication of the disease will become unless the insects are suppressed. The harmlessness of mosquitoes in regions still free from malaria is a well-established fact. Whether they can perpetuate their own infectiousness, either by transmission of the sporozoa from brood to brood or by using some susceptible animal as host, the future must settle with the other factors of the problem. Experiments with ticks point to a loss of infectious power when they are restricted to Northern animals, but no absolute proof of this has yet been published. The appearance of malaria during the work of excavation I attribute first to the introduction of the blood parasite into the bodies of chronically infected workers, and secondly to the accessibility of these to the insects, owing to the favorable conditions usually created during such work for breeding and for stinging the unprotected workers. This hypothesis embraces all those conditions and phenomena regarded as neces-

† The persistence of the blood parasite in highly immune cattle and the infectious character of their blood must be rather discouraging to those who look forward to a malarial antitoxin.
sary by older theories, but it interprets them differently. It is based wholly on analogy with Texas fever.

The assumption that attacks of malarial disease beget immunity is not at all weakened by the occurrence of relapses. It should be remembered that the quinine treatment interferes with the immunizing process. In the second place, relapses may simply mean a temporary interference with the protective mechanism, a congestion or temporary stagnation of the blood somewhere which enables the parasite to get at the red corpuscles in defiance, perhaps, of the leucocytes for the time being. It is along such lines of reasoning that we can explain the attachment of the South to the hydric theory of malaria. The bad ground water produces digestive derangements in individuals already infected, and an attack of malaria is called forth. That the human beings of warm climates may not harbor malarial parasites as universally as their cattle do the Texas fever organism remains to be seen.*

The clinical expression of acquired immunity does not seem to have been studied, but it deserves attention and may lead to valuable results. Certainly the analogous conditions in the cattle malaria cited above should stimulate such studies. In the examination of blood films from cases of tertian malaria occurring in a town which has been infected with it for a number of years, it has seemed to me as if in the repeated attacks of permanent infections the parasites were so scarce in the peripheral circulation that they could not be found, although the physician who has had much experience feels positive of the character of the disease. Here we are confronted by the probability that the parasites, frequently so abundant in the peripheral circulation, are gradually confined by the growth of immunity to some restricted territory representing the locus minoris resistentiae during derangements of health.

The recent investigations of Ross, confirmed and materially extended by Koch and his colleagues,† showing that in the Proteosoma infection of certain birds the blood parasite completes its cycle of development in one and the same insect by reappearing finally in the salivary glands, so that the insect becomes infectious a certain number of days after drawing infected blood, introduces a most interesting modification of the course pursued by the blood parasite in Texas fever. In the insect the absorption and dispensing of the infection is made possible by the powers of locomotion. In the obligatory parasitism of the tick the only mode of transmission possible is through the following generation. Evidently the former is the earlier process, the latter the modification which became established during the evolution of obligatory parasitism in the cattle tick. If the life cycle of the malaria parasite should be found the same as that of the Proteosoma of birds, the hypothesis of the transmission of the blood parasite to the immediate progeny of the infected mosquitoes need not be abandoned unless demonstrated to be false. In my field observations the peculiar distribution of cases of tertian fever in a newly infected territory seemed to point to the scattering of an infected brood rather than to the direct transmission from one individual to another. Both modes of dissemination may eventually be found in use.

In presenting these hypotheses I must beg your indulgence, for, setting aside certain very important exceptions, the making of hypotheses is usually a less arduous task than the process of demonstrating their truth. However, I am strongly convinced that the time has come for public health authorities to take some definite stand on this matter of the spreading of tertian malaria in our own climate. The eradication of this and severer forms from the tropical colonial possessions of northern nations may be destined to remain a pious wish, and the exploiting of the natives and their induction into the advantages of our social and political organization may have to be left, as heretofore, to a few hardy pioneers, or to "immunes." At any rate, this is the only comfort we can get from Nature herself just at present. In our own climate, however, it is not too late to stay the diffusion of malaria, and vigorous efforts to that end should be made, both by popular instruction and with the help of sanitary engineering.

Much of the evil which manifests itself in the increasing prevalence of the mosquito is due to the carelessness and indifference of private persons, corporations, and even public authorities, who create and perpetuate the conditions which favor the sitting up and the partial drying up of our streams and smaller water courses and the stagnation of surface water. The inoculation theory of malaria is a safe one with which to begin the warfare against this disease, as it has the support of analogy, of partial demonstration, and of almost all the older theories.

EUDOXINE IN PÆDIATRIC PRACTICE.

By GUSTAVUS M. BLECH, A. B., M. D., CHICAGO.

About a decade ago iodoform was considered one of the most useful antiseptics known to medicine and surgery. Its many objectionable features, such as bad taste and odor, toxicity, etc., have prevented its becoming a panacea for certain affections due to germ infection.

Modern chemists, recognizing the value of iodoform, have tried to produce substitutes which, while equal in efficiency, should be free from its objectionable properties.

* In a recent article (Yearbook of the Department of Agriculture, 1898, p. 466) Norgaard cites facts which show that Texas fever in a fatal form may be developed in apparently immune cattle by sudden extreme changes of temperature and by treating them with oil to remove the ticks.
† Deutsche medicinische Wochenschrift, 1899, February 2.
In pediatric practice the non-toxicity of a given drug is almost a *conditio sine qua non*.

Iodol, aristol, europhen, and nosophen are familiar synthetically produced derivatives of iodine which have of late become familiar to the medical profession.

Clinically, as a dusting powder for wounds, chancre-ulcers, etc., nosophen certainly has proved itself superior to the others in my practice, and it is my acquaintance with nosophen which led me to investigate clinically the merits of its bismuth salt, eudoxine, in a certain class of diseases of children.

Nosophen is a tetraidophenolphthalein of the formula—

$$C_{16}H_{14}O_{11}$$

$$C_{16}H_{14}O_{12}$$

$$C_{16}H_{14}O$$

$$C_{16}H_{14}O_{10}$$

It is obtained by the action of iodine on solutions of phenolphthalein.

Eudoxine is a reddish-yellow powder, tasteless and odorless, insoluble in water. On reaching the acid stomach the bismuth contained in eudoxine becomes separated from it and stable bismuth compounds are formed by the gastric juice which exert a favorable action in diseased conditions of the stomach. The nosophen contained in eudoxine passes unaltered through the stomach, but during absorption in the alkaline intestine it is changed into its sodium salt—namely, antinosine—this being held in solution and acting as a disinfectant on the bacilli and their toxins found in the intestinal tract.

Antinosine is soluble and decidedly antiseptic, in the fullest sense of the term, for it not only checks the growth of bacteria and their toxins but annihilates them. It is non-toxic, large doses injected into the system of several small dogs having failed to produce any ill effects.

Eudoxine in its original state contains fifty per cent. of iodine and only about nineteen per cent. of bismuth. We can see from this that we have nothing to fear from the latter constituent, in very small children, even if eudoxine is administered in large doses.

The same statement is made by Rosenheim, who has given the drug a thorough trial in Senator's clinic, and is corroborated by Binn and Zuntz, who have made a series of animal experiments and bacteriologic examinations. Schön-Ladniewski, in the *Wiener medizinische Presse* (No. 45, 1897), reports fifty-eight cases treated with eudoxine, and concludes his opinion on the drug thus:

"It would be a mistake to regard eudoxine as a universal remedy for all intestinal affections. Basing on my experience, I can state that eudoxine can be employed successfully only in cases in which the evacuations are mixed with mucus or pus."

I fully concur in Ladniewski's views, but must add that I have observed good results in all forms of infantile diarrhoea, even when the evacuations were tinged with blood.

It would be impossible to report all my observations. Covering a period of almost three years and numbering sixty-three. Many cases offering no unusual clinical features were merely marked in the visiting list, so that the diagnosis, length of disease, and final result only were noted. One case, however, is of some interest, and as I remember the details will give them in full. A tabulated list of the others will have to suffice.

I. Sz., female, Polish, aged thirteen years (Detroit), suffered from a severe diarrhoea accompanying pulmonary tuberculosis. The parents having implored the attending physician to check the diarrhoea, which seemed to prostrate the child, he prescribed bismuth subnitrate, salol, naphthol, and irrigation. The patient received a proper diet, and when I saw her lime-water and milk were given, but the diarrhoea persisted. Being in the neighborhood attending a surgical case, I was called in, absence of the physician being given as the reason.

I prescribed eudoxine, five grains every three hours, and left a note for the attending physician. This was at 11 A.M. (June 6, 1897). The next afternoon the father called at my office and wanted me to take charge of the case, "my prescription having struck the disease," as he expressed it, the diarrhoea having practically ceased.

It is needless to add that I refused to take charge of the case. The attending physician told me later that the patient lived about two months after that incident.

This case certainly illustrates the superiority of eudoxine over the other drugs prescribed by the physician in charge of the case.

The ages of the other sixty-two children ranged from four months to nine years and three months. Ileocolitis was diagnosed forty-two times; acute dysentery, three times; chronic dysentery, once; diarrhoea accompanying miliary tuberculosis, twice; and catarrhal enteritis fourteen times.

Of these diets: One patient of acute dysentery, seen on the tenth day of the disease, the cases accompanying miliary tuberculosis (although the diarrhoeas were checked in from twenty-four to seventy-two hours), and one child, aged nine months, from acute ileocolitis, seen on the sixth day and diagnosed by the attending physician as "cholera infantum."

Recoveries took place: Thirty-eight in twenty-four hours, twelve in two days, two in three days, and six in four days.

**Tilly's Tonic Pills.**—The formula is thus given in the *Riforma medica* for April 4th:

R Strychnine sulphate ..... 0.30 of a grain;
Quinine sulphate,
Extract of hyoscyamus, each 15 grains; mus.
Reduced iron .............. 9 "

M. Divide into ten pills. One to be taken daily.
THE DOCTOR AS A CARRIER OF DISEASE.*

By JOHN T. HOWELL, M.D.,
NEWBURGH, N. Y.

In these times of successful quarantine and disinfection there yet remains a much-neglected danger, which every physician, to be consistent, should carefully consider and endeavor to prevent.

We have fought with pride the victorious battles against sepsis and contagion and have drawn the restrictions more and more tightly about quarantined patients, until they are beginning to dread the deprivations entailed almost as much as the disease itself. But this, we philosophize, is a necessary alternative, and not even our patients would be willing to turn back to the old way by which disease was so widely spread.

The optimist avers he can almost see the dawn of contagious immunity; but I think it is evident that that goal can not be reached until there is maintained a more perfect barrier against contagion than the following familiar picture illustrates:

A doctor is called to see a case of scarlet fever. He announces his diagnosis and recommends that the patient be strictly quarantined in a room with a special nurse, who must change her clothing whenever leaving the room, and must avoid contact with other persons, especially children. These and many other necessary restrictions on the part of the family are faithfully carried out during the whole period of the disease.

The doctor meanwhile visits his patient frequently, and in examining the throat and body comes more or less in contact with the contagion, especially by means of his clothing, which he does not change or disinfect before leaving the house.

It has been asserted in the past, even by eminent authority, that contagion could not be sufficiently impregnated by such exposure as to be carried away; but in the light of the researches of to-day such statements hardly need to be discussed. Certainly the doctor's person or clothing has not yet been proved to be immune from contagion, and I fear that a careful examination of his coat sleeves would reveal a startling number and variety of such disease germs.

Fortunately, his patients have a vigilant protector in resistentia naturae, although the physician must occasionally sow some seed in the fertile soil with which he so often comes in contact. When we consider the possibilities of a contagious-disease germ—its vitality, reproductive powers, and the destruction it may cause—our responsibility as sentinels overshadows all other considerations.

Another way by which the doctor may carry disease is on his hands, especially under his nails; and the difficulty with which their proper disinfection is accomplished makes them a frequent source of infection.

Much has been accomplished by the emphasis which has been put upon this danger, but still there are physicians who continue most careless about this source of infection to their patients. I suppose many a physician would scoff at or resent the suggestion that he should wear his hair closely trimmed and beard shaven; but a second thought must convince him that the idea is in no way extreme. Then, too, his thermometer, hypodermic syringe, medicine case, prescription book, and many other daily necessities need to be watched, as they are used about from house to house and may easily become carriers of disease. All of these channels through which contagion or sepsis might be, and I believe often are, spread are well enough known, but so generally overlooked that I have thought it important to bring the danger to your attention, and at the same time offer some suggestions as to ways in which they may be averted.

In regard to contagion, it has been shown that it travels chiefly along certain well-known channels; and I believe were our energies bent almost wholly toward the control of these, many of the rigorous restrictions of the present system of quarantine might be safely relaxed. Physicians should point out these sources of danger and endeavor to educate the public to understand that it has only these to really fear, and that it is the same with contagion as in other matters—probable dangers, not possible ones, warrant attention.

The doctor in attendance upon a patient suffering from a contagious disease is most liable to carry the germs away upon his clothing, and therefore that should be properly protected, especially at those times when the contagion is most actively thrown off.

For this purpose I have worn for a number of years past a gossamer rubber overcoat, which forms a perfect protection, and because of its lightness is very convenient. A complete covering would include a hood for the hair; but with care its use is seldom necessary. With such an impervious protection, and care to avoid unnecessary contact with the patient, the doctor, after having disinfected his hands (and face, if need be), can leave the room, hang up his coat in some place provided near by, and walk out of the house conscious that he does not carry with him any of the dread contagion.

I keep two or more such coats on hand, which are thoroughly disinfected after each case, and when rolled up occupy the space of the smallest kind of a bundle in my carriage.

For the disinfection of clothing, when from any accident that may become necessary, the use of formaldehyde gas is undoubtedly one of the best means we now have.

It in no way injures fabric, and therefore can be safely used to disinfect anything which can not be subjected to heat. Sterilization by high temperature is the crucial method, but obviously can be used but in a limited way for one's personal needs.

* Read before the Medical Society of the County of Orange, N. Y., May 2, 1899.
The rubber-tissue finger cots afford us a most practical and efficient protection. They protect our fingers from infectious wounds or when making orificial examinations; and when the cots have been sterilized they will protect an aseptic wound from any infection that may be upon our fingers.

The use of these and rubber gloves has at least made it possible for us to have sterile hands at any time, and they form the last link needed to perfect an aseptic surgical technique.

While the control of contagion is not so wholly within our power as that of infection, the powerful reenforcements we have received from antitoxines promise to relegate, in time, diphtheria, and perhaps scarlet fever, to the place of small-pox.

But as the control of small-pox, we should remember, was not accomplished alone by vaccination, so must the troublesome methods of quarantine and disinfection continue to be employed in the warfare against other contagious diseases.

With such a victory in view, we should renew our courage and so strengthen all of these weapons that they shall be impervious to those darts from which we have in the past failed to shield our patients.

---

**Therapeutical Notes.**

**For Nephritis.**—The *Progrès médical* for June 3d attributes the following to Huchard:

- Tincture of grindelia robusta 450 grains;
- Tincture of convallaria majalis 150 “;
- Tincture of squills 75 “.

M. Fifteen drops to be taken three times daily.

**An Application for Urticaria.**—The *Reforma medica* for May 9th attributes the following formula to Gaucher:

- R Alcohol, Chloroform, Sulphuric ether, each 3 parts;
- Menthol 1 part.

M. To be applied in the form of spray.

**Iron and Cascara in the Treatment of Chlorosis.**—The *Reforma medica* for April 11th gives Liégeois's formula as follows:

- R Iron sulphate 75 grains;
- Sugar of milk 2.25 “;
- Powdered cascara sagrada 3.75 “.

M. Divide into a hundred powders. One to be taken after each meal.

**Menthol in the Treatment of Insect Bites.**—The *Gazette hebdomadoire de médecine et de chirurgie* for April 30th gives this formula:

- R Menthol 1 to 2 parts;
- Sulphuric ether 10 “.

M. To be applied lightly with a camel's-hair brush. Not to be used near the eye.

**NEW YORK MEDICAL JOURNAL.**

*A Weekly Review of Medicine.*

Published by

D. APPLETON AND COMPANY.

Edited by

FRANK P. FOSTER, M.D.

NEW YORK, SATURDAY, JULY 8, 1899.

**THE RANK OF THE SURGEON-GENERAL OF THE ARMY.**

We have long held that the present rank of the surgeon-general of the army, that of a brigadier-general, was not high enough to be commensurate either with the dignity and importance of the medical corps or with the capabilities required in the incumbent of the office. We are glad to see that at its recent annual meeting the Medical Association of Georgia took action that ought to result in bringing home forcibly to the profession, and, through them, to congress the urgent need of according higher rank to the surgeon-general. We are indebted to the association's secretary, Dr. R. H. Taylor, for a copy of certain vigorous resolutions passed at the Macon meeting. They set forth that the office of surgeon-general of the army involved great and grave responsibility and the direction of vast interests, and called for the highest order of professional skill, learning, and executive ability; also that the number of officers and soldiers under the direction of the surgeon-general in an army organized like that of the United States was greater than that under a division commander; and that it was the sense of the association that the surgeon-general should have the rank, pay, and allowances of a major-general. The meeting further resolved to send copies of its resolutions to the president of the United States, to the secretary of war, to the Georgia senators and representatives in congress, and to all the medical societies of the United States requesting them to join in the association's appeal.

The committee appointed to communicate this action to other medical bodies is doing its work promptly and most commendably. The chairman, Dr. J. Lawton Hiers, of Savannah, makes the forcible remark that members of the profession who are likely to be called to the office of surgeon-general must make a sacrifice in income when they are so called, even if the rank, pay, and allowances are raised to those of a major-general, and that that consideration as well as the dignity of the profession requires, in the association's unanimous opinion, the elevation sought for. We do not see that these arguments can be refuted, and we are heartily in
accord with the Medical Association of Georgia in its effort to secure the cooperation of other medical societies. We would, indeed, go further, and urge upon individual physicians the duty of exerting what influence they are capable of upon their congressmen to endeavor to bring about the proposed elevation of the office of surgeon-general of the army.

THE INSANITY PROBLEM.

It is not probable that we shall ever wholly succeed in protecting person and property against the first violent manifestation of unrecognized insanity, but all persons who have once been shown to be insane, even if only temporarily, should be kept under competent supervision and such restraint as may be found necessary. There should be no known lunatics at large, however "harmless" they may be rated. The public hardly seems to appreciate the danger it is in from the outbursts of insane propensities, and this, it is to be suspected, is in great measure due to the community's sense of self-preservation having been drowned in a sentimentality that has been aroused and is continually nourished by harrowing tales of sane persons wrongfully immured in asylums and of the cruelties alleged to be practised in such institutions. Nevertheless, the danger is great. A recent writer in the Irrenfreund, whose article is reproduced in the Medicinisch-chirurgisches Central-Blatt for April 14th, points out that accounts of outrages by lunatics are daily to be found in the newspapers in Germany, and that Les Aliénés en liberté is a standing headline in the great French journals of psychiatry. He cites an instance in which a young man's offenses in several German towns have been conditioned on the score of his insanity, and yet he is still at liberty.

But the great asylums are full almost everywhere. What is to be done? Shall we establish great colonies for the insane like the one at Dun-sur-Auron, in France? In the Progrès médical for June 3d the editor, Dr. Bourneville, the well-known alienist, says that the insane there colonized complain bitterly of their exile and of their not being able to receive visits from their friends. The "family treatment" of the insane—that is, their maintenance and protection in family establishments, either their own or those of strangers—will apparently have to be resorted to on a larger scale than it has been heretofore. It is favored by the German Reichstag, but the writer in the Irrenfreund hints that the degree of medical supervision provided for is inadequate, not necessarily amounting to more than an examination once a year by the district physician. The problem of the family treatment of the insane has been earnestly studied by a number of French psychiatrists of distinction, particularly Dr. Cullere and Dr. Bourneville, and the prevailing opinion among them seems to be that that form of management is applicable to a large percentage of the insane, especially at the beginning of their malady, but that it should not be carried out in their own families, but in those of strangers living within easy access of some large asylum, so that the patients may at all times be under adequate medical supervision. Experience in various countries seems to show that this is the best solution of the insanity problem at present attainable, though of course eternal vigilance is required in carrying out the plan.

THYROID MEDICATION TO HASTEN THE UNION OF BROKEN BONES.

There is perhaps some danger that, from having been contented for centuries with looking upon the thyroid gland as of no consequence, we may go to the opposite extreme of expecting it to accomplish things utterly beyond its power. In the Écho médical du nord for June 11th Dr. Lambret, chief of the surgical clinic of Lille and a railway surgeon, expatiates upon this proposition, and then comes down to the matter of the influence of the internal secretion of the gland on the osseous system. He is at some pains to recapitulate the leading observations on which we rest our present views of the part played by the thyroid in increasing the stature by its action and of the relation of its defective action to dwarfing, rickets, cretinism, myxoedema, etc. He recounts, in particular, that in 1895 Hanau and Steinlein reported to a congress held in Frankfort their observations of the tardiness of the union of broken bones in animals that had been deprived of the thyroid gland, and suggested, as a corollary, the use of thyroid medication for promoting the formation of callus; also that in 1897 Gauthier recorded in the Lyon médical his successful adoption of this hint in practice, a course which Quéén and Folet, too, found efficient, although the last-named gentleman failed with it in one instance. There is good reason, then, to look upon thyroid medication as likely to prove of service in cases of delayed union of fractures.

But this is not all. There appears to be some ground, in the shape of a case reported by the author, for hoping that the same treatment may so hasten the union of broken bones as to shorten materially the time usually required for their repair, although he admits
that no broad conclusions should be drawn from a single instance. The case was that of a man whose tibia and fibula were broken in a car-coupling accident. On the day after the injury he was put upon the use of capsules each containing three grains of thyroid gland, three daily. On the seventeenth day union was found to be solid. All appliances were removed, and the man was allowed to get up. In these days of time-saving it is assuredly worth while to resort to Dr. Lambert’s treatment in cases of fracture, and it ought not to take long to estimate its value.

SYSTEMIC REMEDIES IN DISEASES OF THE TEETH.

In a paper recently read before the Philadelphia Academy of Stomatology, Dr. Leo Greenbaum (International Dental Journal, May) calls attention to the valuable aid that may be lent by internal medication to local measures in painful conditions accompanying dental diseases. He speaks highly, in hypersensitive dentine, of the excellent results obtained from the use of asafetida, and gives an instance in which the administration of two three-grain asafetida pills, the first an hour and the other half an hour before the time appointed for operation, induced ready submission to operation in a patient so sensitive that any exploratory manipulations had been previously out of the question. The coal-tar derivatives, acetanilide, phenacetine, etc., are very useful in quieting the reflex face pains of pulp diseases, and giving time for the arsenical or other local application to produce its effect. The author particularly praises the combination of small doses of synergists of this character (as advocated by Dr. Scheinikman in our issue for February 18th). It is obvious that physicians, especially in country places, can do much to relieve the suffering of such patients without the too commonly resorted to treatment of extraction, thus gaining time till the services of a dental surgeon are available.

A GOITROUS TUMOR OF THE KIDNEY.

A singular case of “aberrant goitre” of a malignant nature is reported by Dr. W. Sykow (Archiv für klinische Chirurgie, lviii; Annales des maladies des organes génito-urinaires, May). A woman had a large tumor of the left kidney. The organ was removed, and its exterior showed a number of cysts containing a yellowish liquid. The suprarenal capsule was occupied by a tumor about three inches long and two inches wide, also yellowish, which had penetrated into the kidney and occupied the upper third of the gland. Nodules resembling it were found in other parts of the kidney.

SUDDEN BLANCHING OF THE HAIR.

Accounts of the hair suddenly turning gray in consequence of intense emotion are generally taken with a grain of salt, and it was perhaps in a skeptical frame of mind that the venerable Professor Virchow some years ago requested physicians who knew of such cases to report them to him. Acting on this invitation, Dr. Moritz Schmidt, of Frankfort-on-the-Main (Archiv für pathologische Anatomie und Physiologie und für klinische Medicin, ciii. 1), reports the case of a man in whose hair two white patches appeared on the day after a railway accident by which he was very much frightened.

A MAKER OF FREAKS.

We find in the Gazette medicale de Paris for June 3d a somewhat humorous account of a man named Scheard, of London, whose regular occupation seems to have been that of making models of monstrosities for anatomical museums, but who is said also to have produced freaks among living animals by vivisectional procedures. He was reputed to profess his ability to make living human monstrosities, but to have refrained from trying for fear that such an industry would be stigmatized as criminal.

THE CUTANEOUS ABSORPTION AND RENAL ELIMINATION OF IODINE.

At a recent meeting of the French Academy of Sciences (Gazette hebdomadaire de medicine et de chirurgie, May 15th) Dr. F. Gallard made a curious observation concerning the elimination in the urine of iodine absorbed through the skin, namely, that the amount eliminated did not increase gradually but by successive jumps, so to speak.

SANITATION IN BOGOTÁ.

Dr. J. Navas, in a communication to the Bogotá Academy of Medicine (Revista Médica de Bogotá, February), draws a vivid picture of the obstacles that the sanitary officials have had to encounter, many of which, we are happy to learn, they have overcome. He closes with the warning that habitual neglect of hygiene leads to degeneracy, and degeneracy to brutishness and idiocy.

THE BOGUS WORD “CURETTEMENT.”

We sympathize entirely with Dr. Fehling in his objection to such terms as “curettement,” “morcellement,” and the like (Centrillblatt für Gynäkologie, June 17th). He shows that curettement is the proper word for “curettement,” and we may add that morcelation is better than “morcellement.” Fehling cites Pinard as distinguishing between curettage (done with the curette) and curage (done with the fingers).

SAFETY ELEVATORS.

The recent deplorable accident whereby a young woman was thrown out of an elevator which started, as it would seem, before the gate was closed, injuring her so severely that she died in hospital in a very short time, calls attention to the fact that there is in existence, we believe, and in use even in this city, a device whereby an electric circuit made by the shutting of the gate sets the elevator in motion. It seems to us that some such device should be universally adopted, for elevator accidents appear to recur with disquieting frequency.

TWO NEW SIGNS OF DEATH BY SUBMERSION.

According to the Revue médicale for June 14th, M. Moreau (Abbeille médicale) reported at a recent meeting of the Medico-legal Society of Belgium two new
signs of death due to submersion. The first consisted of the presence of a clear, limpid fluid in the peritoneal cavity, and the second of a great quantity of clear, pale urine in the bladder. The explanation of these signs appears to be that in the act of drowning a considerable quantity of fluid is taken in by the digestive and respiratory tracts and, finding its way quickly into the circulation, causes great internal pressure with consequently increased transudation in the capillary mesh-work of the kidneys and peritoneum. The author says that while the bladder secretion is occasionally wanting, that of the peritoneum is rarely absent. These signs may be of service as confirmatory evidence, but it is obvious that they are so liable to production from other causes that they would not seem to possess any great substantive value.

A COLORED MEDICAL MISSIONARY.

We are glad to see that a number of influential citizens of New York, including several physicians, are taking an interest in the effort of Dr. J. Albert Thorne to collect a fund to enable him and a party to go to Africa and labor for "the temporal and spiritual advancement of the African race." Under the auspices of the New York Preachers' Association a public meeting to further the enterprise was held in Mount Olivet Church on Thursday evening, July 6th. Dr. Thorne, a negro himself, is a West Indian by birth and a graduate in medicine of Edinburgh University.

SUDDEN EXOPHTHALMIA FROM DISEASE OF THE FRONTAL SINUS.

In our issue for July 1st we referred to a case of occasional displacement of the eyeball in a glassblower. An example of exophthalmia coming on suddenly as a result, apparently, of acute inflammation in the frontal sinus is reported by M. Jacqueau (Lyon médical, June 11th). The eye was forced downward and outward, as well as forward, and a puffy mass could be felt in the space between the globe and the upper and inner wall of the orbit. The author does not think there was a direct communication between the orbit and the frontal sinus, but that the inflammation passed through the bony barrier intervening.

PROTECTIVE INOCULATION AGAINST THE TEXAS CATTLE FEVER.

In the Proceedings of the Royal Society for May 25th there is an encouraging account by Alexander Edington, M. B., F. R. S. E., director of the Bacteriological Institute, Cape Colony, of certain results of a method of protective inoculation by intravenous injections of defibrinated blood from infected animals. "In May, 1898," he says, "I inoculated ten head of old cattle with blood from an animal which had been inoculated, six months previously, with virulent blood. These cattle were immediately removed from the institute, and later sent to an infected area in company with ten head of young animals which were un inoculated, but, as is commonly known in this colony, are not so liable to death from this disease as are older animals. Of the young stock all have been infected by exposure in the veld, and three have died. Of the older, more susceptible, animals not one has shown the slightest signs of illness, and the cows have given birth to healthy calves."

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 1, 1899:

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, cholera, plague, and leprosy were reported to the surgeon-general during the week ending July 1, 1899:

Small-pox—United States.
- Evansville, Ind.: June 16-24: 1 case.
- Kansas City, Kan.: June 16-22: 2 cases.
- New Orleans, La.: June 16-24: 2 cases.
- Boston, Mass.: June 24: 2 cases.
- Fall River, Mass.: June 21: Total to date, 34 cases.
- Appleton, Minn.: June 16: 1 case.
- Worthington, Minn.: June 16: 5 cases.
- Farmington, Mo.: June 16: Reported.
- St. Louis, Mo.: June 19: 9 cases.
- Omaha, Neb.: June 10-17: 2 cases.
- New York, N. Y.: June 17-24: 2 deaths.
- Philadelphia, Pa.: June 24: 1 case.
- Pittsburg, Pa.: June 16-17: 1 case.
- Ponce, Porto Rico: June 10: 1 case.
- Cleveland, Ohio: June 3-17: 13 cases, 1 death.
- Columbus, Ohio: June 16-25: 1 case.
- Massillon, Ohio: June 17: 1 case.
- Greenwich, S. C.: June 10-17: 1 case.
- Newport News, Va.: To June 24: 683 cases, 14 deaths.
- Norfolk, Va.: To June 22: 682: 14 cases.
- Portland, Va.: To June 22: 344 cases, 5 deaths.
- Spokane, Wash.: June 17: 1 case.

Small-pox—Foreign.
- Antwerp, Belgium: June 3-10: 2 cases, 1 death.
- Rio de Janeiro, Brazil: May 5-19: 60 cases, 20 deaths.
- Nuevitas, Cuba: June 16: 1 case.
- Cairo, Egypt: May 22-June 3: 4 cases.
- Athens, Greece: June 3-10: 18 cases, 7 deaths.
- Bombay, India: May 23-30: 9 cases.
- Madras, India: May 13-26: 3 cases.
- Moscow, Russia: May 27-June 3: 34 cases, 7 deaths.
- Odessa, Russia: June 3-10: 6 cases, 3 deaths.
- St. Petersburg, Russia: May 27-June 3: 25 cases, 5 deaths.
- Warsaw, Russia: May 27-June 3: 1 death.
- Glasgow, Scotland: June 3-10: 1 case.
- Smyrna, Turkey: June 3-10: 1 case.

Yellow Fever—Foreign.
- Rio de Janeiro, Brazil: May 6-19: 34 cases, 17 deaths.
- Havanna, Cuba: June 8-15: 1 case.
- Matanzas, Cuba: June 20: 1 case.
- Santiago, Cuba: From outbreak to June 26: 35 cases, 11 deaths. All but 4 were among troops.
- Tampico, Mexico: June 3-9: 2 cases.
- Vera Cruz, Mexico: June 8-22: 79 deaths.
Ochlera.
Bombay, India............. May 23-30........ 2 deaths.
Madras, India............. May 20-26........ 6 "

Plague.
Bombay, India............. May 23-30........ 124 deaths.
Madras, India............. May 20-26........ 1 death.
Bushir, Persia............ June 8............. 1 case.

Leprosy.
Eagle Pass, Texas........ June 30............. 1 case.

Change of Address.—Dr. J. B. Gregg Curtis, to No. 312 Fifteenth Street, McPherson Square, Washington, D. C.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 24 to July 1, 1899:

APPEL, DANIEL M., Major and Surgeon, is granted leave of absence for two months.
COONEY, DANIEL C., Acting Assistant Surgeon, is assigned to duty in the office of the chief surgeon, Matanzas, Cuba, as assistant sanitary inspector.
FRAUNBERGER, POWELL C., First Lieutenant and Assistant Surgeon, and FORD, JOSEPH H., First Lieutenant and Assistant Surgeon, will proceed to the Philippine Islands on the transport Sheridan.
GREENLEAF, CHARLES R., Colonel and Assistant Surgeon-General, is announced as sanitary inspector of the camps of the returning volunteer troops.
KRANE, S. P., Major and Surgeon, will proceed to Camp Young, Guanayaj, and Camp Egbert, Pinar del Rio, for the purpose of making a medical and sanitary inspection of the hospitals and camps located there.
THOMASON, HENRY D., Surgeon, United States Volunteers, will report to the commanding officer, Tenth Cavalry, to make the physical examinations of the veterinaries of that regiment.
WILSON, ROY A., Acting Assistant Surgeon, will proceed to Willet’s Point, New York.
WILSON, WILLIAM H., Captain and Assistant Surgeon, will proceed to the Presidio, San Francisco, for duty at the camp of recruits.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending June 29, 1899:

SAWTELL, H. W., Surgeon. Detailed as inspector of relief stations of the third and fourth class.
WOODWARD, R. M., Passed Assistant Surgeon. Upon being relieved by THOMAS, A. R., Passed Assistant Surgeon, to proceed to Washington, D. C., for assignment to duty.
THOMAS, A. R., Passed Assistant Surgeon. Upon being relieved by VAUGHN, G. T., Passed Assistant Surgeon, to proceed to Recy Island Quarantine Station and assume command of the service.
HALL, E. B., Acting Assistant Surgeon. Granted leave of absence for three days from June 4, 1899.
WALKLEY, W. S., Acting Assistant Surgeon. Granted leave of absence for three days from June 28, 1899.
BROOKS, W. E., Sanitary Inspector. Granted leave of absence for three days from June 28, 1899.
RODMAN, J. C., Sanitary Inspector. Granted leave of absence for seven days from June 27, 1899.

THURSTON, E. J., Hospital Steward. To proceed to New York for special temporary duty.

Promotion.
PETTUS, W. J., Passed Assistant Surgeon. Commissioned as surgeon.

Appointment.
TOWNSEND, FREDERICK, of Michigan, to be acting assistant surgeon, United States Marine-Hospital Service, for duty at Sault Ste. Marie, Michigan.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Week ending July 1, 1899:

BELL, W. L., Assistant Surgeon. Detached from the Naval Hospital, Mare Island, California, and ordered to the Philadelphia.
BOGAN, F. M., Assistant Surgeon. Ordered to additional duty at the Boston Navy Yard.
BRODMICK, R. G., Passed Assistant Surgeon. Ordered to Washington, July 6th, for examination for retirement, and then home to await orders.
ODELL, H. E., Assistant Surgeon. Detached from the Philadelphia and ordered to the Naval Hospital, Mare Island, California.
ROSENBERG, J. C., Passed Assistant Surgeon. Detached from the Buffalo, when put out of commission, and ordered to the Vermont immediately.

Society Meetings for the Coming Week:
MONDAY, July 10th: New York Academy of Sciences (Section in Chemistry and Technology); New York Medico-historical Society (private); New York Ophthalmological Society (private); Gynaecological Society of Boston; Burlington, Vermont, Medical and Surgical Club; Norwalk, Connecticut, Medical Society (private).
TUESDAY, July 11th: Medical Societies of the Counties of Chautauqua (annual), Clinton (semiannual), Greene (quarterly), Jefferson (semiannual—Towetown), Madison (annual), Oneida (quarterly—Utica), Ontario (annual—Canandaigua), Rensselaer, Schuyler (semiannual), Tioga (semiannual—Owego), and Wayne (annual), New York; Newark (private) and Trenton. New Jersey, Medical Associations; Clinical Society of the Elizabeth, New Jersey, General Hospital and Dispensary; Northwestern Medical Society of Philadelphia; Practitioners’ Club, Richmond, Kentucky; Richmond, Virginia, Academy of Medicine and Surgery.
WEDNESDAY, July 12th: American Microscopic Society of the City of New York; Society of the Alumni of the City of New York; Tri-State Medical Association (Port Jervis), New York; Franklin, Massachusetts, District Medical Society (quarterly—Greenfield); Hampshire, Massachusetts, District Medical Society (quarterly—Northampton); Worcester, Massachusetts, District Medical Society (Worcester); Kansas City, Missouri, Ophthalmological and Otological Society.
THURSDAY, July 13th: Brooklyn Pathological Society; Medical Society of the County of Cayuga, New York; South Boston, Massachusetts, Medical Club (private).
FRIDAY, July 14th: German Medical Society of Brooklyn; Medical Society of the Town of Saugerties, New York.
MARRIAGES AND DEATHS.—LETTERS TO THE EDITOR.

BIRTHS, MARRIAGES, AND DEATHS.

Married.

BAUGH—WILLIAMS.—In Berwyn, Pennsylvania, on Wednesday, June 28th, Dr. Anthony E. Baugh, of Paoli, Pennsylvania, and Miss Mary Elizabeth Williams.

BENTLEY—MYERS.—In Plattsburgh, New York, on Wednesday, June 28th, Dr. Charles S. Bentley, of New York, and Miss Gertrude Myers.

DAVIS—MUTSCHLER.—In Rochester, on Tuesday, June 27th, Dr. James Clement Davis and Miss Mary Frederica Mutschler.

HUTCHINSON—HUNTINGTON.—In Ithaca, Long Island, New York, on Tuesday, June 6th, Mr. Montrie Brailsford Hutchinson and Miss Katherine Huntington, daughter of Dr. George Huntington.

LYON—JONES.—In New York, on Wednesday, June 28th, Dr. J. F. Lyon and Miss Grace Hamilton Jones.

MARTIN—STARR-KEEPER.—In Providence, Rhode Island, on Wednesday, June 21st, Dr. John Macleod Martin, M. R. C. P. Lond., and Mrs. Elizabeth Starr-Keefer.

RIORDAN—CALDWELL.—In Providence, Rhode Island, on Wednesday, June 28th, Mr. Daniel J. Riordan and Miss Edith Maude Caldwell, daughter of Dr. William M. Caldwell.

SEARS—SALISBURY.—In Boston, on Wednesday, June 28th, Dr. Walter S. Sears, of Worcester, Massachusetts, and Miss A. L. Salisbury.

SMITH—BROWN.—In New York, on Wednesday, June 28th, Dr. Reginald Knight Smith, United States Navy, and Mrs. Alice Scott Browne.

TRAVELL—DAVIDSON.—In Albany, New York, on Thursday, June 29th, Dr. J. Willard Travell, of New York, and Miss Janet Davidson.

Died.

LAMBERT.—In New York, on Sunday, July 2d, Isabelle Chesterman Lambert, wife of Dr. Walter Eyre Lambert.

NOBLE.—In Jersey City, on Thursday, June 29th, Dr. Francis E. Noble, in the seventy-fifth year of his age.

Letters to the Editor.

SUMMER HEAT AND THE SUMMER DIARRHEA OF INFANTS.

144 West Eighty-fifth Street, June 16, 1899.

To the Editor of the New York Medical Journal:

Sir: In an editorial article in the Journal for June 10th on Summer Heat and the Summer Diarrhea of Infants, the idea is conveyed that the main effect of summer heat in the causation of diarrheas in infants consists in the decomposition of cow's milk, and other foods used as substitutes for mother's milk. The position taken in the said editorial assumes to be strengthened by referring to a paper by Dr. Stawell, of Melbourne, published in the Intercolonial Medical Journal for March, 1899. Reference is made to the view that other influences of summer heat upon the infant organism, as a causative factor in the production of summer diarrheas, are now regarded by the best authorities as of minor importance. Such expressions of opinion in a leading medical journal, as yours is, might on first thought not be necessary to be challenged by those of the profession familiar with diseases of children; but when it is considered that many other physicians may be led to follow the announced idea that the all-important question in the prevention of summer diarrheas is to prepare and maintain such food as will best stimulate mother's milk, either by sterilization, pasteurization, percentage modification, or otherwise, without taking into account the direct devitalizing influence of the excessive summer heat, especially in large cities, upon the general physiological mechanisms of the infant organism, then I think it is only right and proper that the other side of the question should be fairly and prominently stated.

It is as important, in my estimation, to provide against the deleterious effect of heat upon the infant's weak constitution as it is important to guard against the entrance of disease-producing germs into the intestinal canal. For if the infant is overfed, for instance, with even sterile food, abnormal intestinal fermentation will occur because the digestive functions of the stomach and intestines will be weakened and poorly performed from the effect of long-continued excessive heat. This fact has been repeatedly demonstrated. We all know that even in the adult hot weather causes a loss of appetite, which is the physiological index of perfect gastric function.

Dr. Stawell's quoted statement that he has never met with a single fatal case of summer diarrheas in an exclusively breast-fed infant must surely imply that it was the skill of the physician that gave him the experience, for no one of any extensive practice among infants in a climate subject to high summer temperature will deny that breast-fed infants do have diarrheas in summer.

Entire attention, in recent years, has been directed toward a proper modification and preparation of artificial foods for infants as a protection against summer diarrheas, and it is about time that attention should also be called toward the equally great importance of keeping the infants as cool as it is possible to do. They are helpless innocents whose heat-regulating centres are weak, and they must be assisted or take chances of dying. The suggestions made by Dr. Chapin, in his most excellent paper recently read before the New York Academy of Medicine, are to my mind of the highest importance, and especially the recommendation he makes for the city authorities to plant trees along our streets in order to cool the air of summer, as well as to furnish shade, absorb impurities from the atmosphere, and beautify the city.

In teaching students at my clinic I endeavor to impress upon them the importance of keeping the infant cool during the heat of summer by every known means, and I am confident that the summer sojourn in the country, where the air is at least cooler at night and at all times purer than in the overheated cities, the wholesome excursions on the water, and the common-sense practice of frequent cool bathing save the lives of infants in summer as much through relief from excessive heat as the being able to use fresh milk from a cow that can be milked twice daily, as explained by Dr. Stawell.

**THE LAW IN ITS RELATIONS TO PHYSICIANS.**

By ARTHUR N. TAYLOR, LL.B.

**XXVI.**

**CIVIL MALPRACTICE, INCLUDING GENERAL LIABILITY OF PHYSICIAN TO PATIENT.**

(Continued from page 28.)

Rules for Determining Skill.—In determining whether or not a physician is possessed of the requisite amount of knowledge, or exercises the proper degree of skill, due regard must be had: First, to the school of medicine which he practises; and, second, to the advanced state of the profession at the time the particular services were rendered.

Practice of the Particular School Governs.—There being different and distinct schools of medicine, recognizing different principles and different modes of treatment, it follows that the treatment of a physician of one school must be tested by the general principles and practice of his own school, and not by those of other schools.*

While the justice and, in fact, the necessity of this law are almost too evident to permit of comment, it will perhaps be desirable to examine one or two cases.

A case in which the rule was extended to a degree to which it could not be at this day, because of the more adequate laws protecting the public from quacks, is that of Bowman vs. Woods.† In this case the defendant claimed to be a botanic physician. The cause of action arose from alleged unskilful treatment of a patient in a confinement case. About thirty-six hours after the delivery a Dr. C was called in as consulting physician, and upon the trial he testified in effect that at the time he arrived the placenta was not removed; that the patient was greatly prostrated by the severity of the labor and the loss of blood; and that she was also suffering from a distention of the bladder, which had not been evacuated since parturition. He gave it as his opinion that the placenta should have been removed and the distended state of the bladder relieved at a much earlier period; and that such delay would be likely to produce puerperal fever. Several other physicians, as witnesses, concurred in Dr. C’s views of the practice.

The defendant then offered as evidence in his own behalf the testimony that he was a botanic physician, and that, according to the botanic system of practice and medicine, it is considered improper to remove the placenta, and that it should be permitted to remain until expelled by the efforts of Nature. The proof of these facts being objected to, they were ruled out by the trial judge. The supreme court, upon reviewing the case, was of the opinion that the trial court erred in not admitting the proffered evidence of the defendant. Justice Greene, after observing that the several schools of medicine were then alike unprohibited and enjoyed equal legal rights in Iowa,‡ said: "A person professing to follow one system of medical treatment can not be expected by his employer to practise any other. While the regular physician is expected to follow the rules of the old school in the art of curing, the botanic must be equally expected to adhere to his adopted method. But on the part of every medical practitioner the law implies an undertaking that he will use an ordinary degree of care and skill in medical operations, and he is unquestionably liable for gross carelessness or unskilfulness in the management of his patients; and still the person who employs a botanic practitioner has no right to expect the same kind of treatment or the same kind of medicine that a regular physician would administer. The law does not require a man to do more than he undertakes, nor in a manner different from that which he professes. Therefore, if in case the defendant below could show that he was employed as a botanic physician, and that he performed the accouchement with ordinary skill and care, in accordance with the system he professed to follow, we should regard it as a legal defense. It would show a full compliance with his profession and undertaking; and if injury resulted from it to the plaintiff, he could properly blame no one but himself.

"The people are free to select from the various classes of medical men, who are accountable to their employers for all injuries resulting from a want of ordinary diligence and skill in their respective systems of treating diseases. It is to be lamented that so many of our citizens are disposed to trust health and life to novices and empirics, to new nostrums and new methods of treatment. But these are evils which the courts of justice possess no adequate power to remedy. Enlightened public opinion and judicious legislation may do much to discourage quackery and advance medical science."

Upon reading this case one can not help rejoicing in the approximate realization of the prophetic hope expressed by the court, for at the present day, excepting in a few States, a defendant would be unable to invoke the protection of an unwilling court by showing that his vicious ignorance of the laws of medicine and of health was sanctioned by the so-called school he professed to follow.

A recent application of the rule is found in the case of Force vs. Gregory.§ There the patient was treated for ophthalmia by the defendant, who is a homoeopathic physician, and who introduced evidence to show that in treating the plaintiff he adopted the remedies prescribed by the homoeopathic practitioners. The plaintiff showed that the old-school practitioners would have treated such a case differently, and that she should have received the latter mode of treatment. The defendant’s counsel asked the court to instruct the jury that the propriety of the treatment of the patient must be tested by the doctrines of the defendant’s school of medicine. The court refused to give the instruction asked, but instead instructed the jury in such a way as to leave it uncertain whether the defendant’s treatment was to be judged by the rules and practice of his own school alone, the instruction given being of the sort calculated to direct the attention of the jury to the relative merits of the two systems. Under this instruction the jury found a verdict for the plaintiff. The supreme court, in reviewing the case, disapproved of the instruction and reversed the judgment. In criticising the instruction given the jury Justice Field said: "The jury, we think, should have been told that the relative merits of the two schools were in no sense before them for their consideration; that so far as the defendant was to be judged by either, it was by the tenets, rules, principles, and practices of his own school, not by those..."

§ Force vs. Gregory, 63 Conn., 167.
of another; and if the defendant adopted the treatment laid down by his own school, the fact that another school prescribed another treatment tended in no wise to show that the defendant was chargeable with lack of skill or negligence. It would seem that if it could be held negligent or unskilful in a given case to use the treatment prescribed by the school to which the practitioner belonged, such negligence or want of skill must consist either in the mode of use, the application of such remedies under improper circumstances, or because they were intrinsically wrong, inappropriate, or inadequate. If there be any valid objection to the language quoted from Patten vs. Wiggin—viz., "The jury are not to judge by determining which school, in their own view, is best—it is in the failure to incorporate with the general statement the further one that the test there given does not exclude the duty of keeping pace with the progress of professional knowledge, ideas, and discoveries, to the extent that a faithful, conscientious, and competent practitioner, of whatever school, may be reasonably expected, and is therefore lawfully required to do."

Perhaps the case of greatest interest recorded in the law reports in which this question was raised is that of Nelson vs. Harrington.* In this case the defendant was a spiritualist or clairvoyant physician. The evidence showed that the patient, a boy of about fifteen years of age, accompanied by his father, called upon the defendant about September 1st. The boy was suffering from a disease of the hip joint, but the defendant diagnosed the disease as rheumatism and prescribed treatment accordingly. He continued to treat the case until about the middle of the January following, and during that time encouraged the patient in persistent walking, asserting that walking was beneficial to him. In January the leg became so much worse that he was unable to walk and suffered great pain. Other physicians were then called in and the patient was benefited, but will remain a cripple for life.

The counsel for the defendant urged that he professed the clairvoyant system of medicine, and that if he treated the patient with due care and skill in accordance with the rules and practice of that school or system of medicine he complied with the requirements of the law and was not liable for unfavorable results of his treatment.

The supreme court, in determining the weight to be given to this defense, carefully reviewed the methods of the alleged school of clairvoyants, which may be described as follows: The mode of diagnosis consists in going into a sort of a trance condition, and while in such state discovering the condition of the patient and prescribing for the malady so disclosed. The spiritualist professes to have no medical knowledge, but trusts implicitly to the correctness of the diagnosis made and prescription given while in such state.

To constitute a school of medicine there must be rules and principles of practice for the guidance of all its members, as respects diagnosis and remedies which each member is supposed to observe in any given case, and each competent practitioner of a certain school would treat a given case in substantially the same way. The court says: "And so one school may believe in the potency of drugs and bloodletting, and another may believe in the principle of similia similibus curantur; still another may believe in the potency of water, or of roots and herbs; yet each school has its own peculiar principles and rules for the government of its practitioners in the treatment of diseases." The court then observes that clairvoyants recognize one mode of practice only to the extent of obtaining a knowledge of the condition of their patients, but that the treatment prescribed by different clairvoyants differs as greatly in similar cases as that prescribed by physicians of entirely different schools, and that by prescribing such different remedies for the same disease they can be said to violate no rule or system of clairvoyant treatment. The court therefore concludes that those practicing medicine as clairvoyants form no school of medicine, and have no particular system or rules by which they can be judged.

Regard must be had to the Advanced State of Medical Science.—The idea expressed by the court in the last part of the quotation from the opinion in the case of Force vs. Gregory brings us to the subject next in order of consideration, which is, that in judging of the knowledge and skill displayed in a given case due regard must be had to the advanced state of medical science at the time the particular services were rendered. In referring to the improvements in medical and surgical science, and the right of the patient to the benefit of these improvements, Justice Woodward said nearly fifty years ago: "Discoveries in the natural sciences for the last half century have exerted a sensible influence on all the learned professions, but especially on that of medicine, whose circle of truths has been relatively much enlarged; and besides, there has been a positive progress in that profession resulting from the studies, the experiments, and the diversified practice of its professors. The patient is entitled to the benefits of these increased lights. The physician or surgeon who assumes to exercise the healing art is bound to be up to the improvements of the day."

The application of the test is very well illustrated in the case of Gates vs. Fleischer.† In this case the plaintiff had recently given birth to a child, from which she suffered a slight laceration of the cervix. Not regaining her strength satisfactorily, she called in the defendant, about five or six weeks after the delivery of the child, to treat her. The defendant made a local examination, and stated that she was suffering from uterine disease, and applied caustics to the cervical canal on the theory that those parts were ulcerated. This treatment was continued for several months.

The defendant, deriving no benefit from this treatment, after a lapse of about eight months consulted a specialist, who found the cervical canal entirely closed. This was opened by artificial means. The evidence also showed that during the entire time of her illness the plaintiff was suffering from septicemia. Upon the trial of the case evidence was given to the effect that the plaintiff had no ulcers upon her uterus or in the cervical canal, and that the treatment with caustics was unjustifiable; that advanced medical science discards the use of caustics in cases of ulceration, as a dangerous practice; and that the treatment applied had caused cicatrization in the cervical canal, etc. The trial court, in instructing the jury upon the law applicable to the case, told them that the physician was bound to bring to the treatment of the case such skill as is ordinarily possessed and exercised by physicians and sur-

Pith of Current Literature.

A Case of Diverticulum of the Oesophagus.—Zahorsky (St. Louis Medical Gazette, May) records a case of diverticulum of the esophagus which from its location he considers unusual. Such diverticula usually occur opposite the cricoid cartilage, and are considered due to a congenital weakness at that point. The patient, a man aged twenty years, was not a subject of tuberculosis or syphilis. There were no stigmata of degeneration. During childhood he used to spit a good deal of mucus and had a disagreeable sensation during deglutition. He had never swallowed any corrosive. For years the difficulty of deglutition had increased, and there was regurgitation of food during or after meals and at bedtime. When the patient attempted to eat he swallowed several mouthfuls, but it all seemed to stop somewhere before it reached his stomach; finally, he swallowed by contracting all the muscles of the neck and fixing his respiratory muscles, and by this extraordinary effort succeeded in forcing the food into his stomach. The case had been diagnostically as stricture, and the patient taught to introduce a hard bougie.

Two facts concerning the patient were definite: First, he had great difficulty in swallowing; second, he regurgitated large quantities of food at various intervals. What pathological condition of the upper alimentary tract could explain these prominent symptoms?

The great difficulty in swallowing could only be explained by a narrowing of the oesophageal canal. What caused this narrowing in calibre? A large hard-rubber bougie was introduced and passed without difficulty into the stomach. The conclusion was inevitable that no organic stricture was present. The contraction in the lumen must, therefore, arise from some tumor pressing on the gullet or, as has been shown in at least one instance, an angular flexure of the esophagus. Finally, spasm of the cardiac orifice must be considered.

In regard to the regurgitation or vomiting of food the question of its source presented itself. If this food came from the stomach the diagnosis of ruminiation seemed probable. A chemical examination of the regurgitated food revealed the starch well digested; entire absence of hydrochloric acid; pepsin not demonstrable; and lactic acid showed a marked reaction by Tiffeman's test; peptones absent. Microscopically starch granules were numerous, but meat fibres were totally undigested. This showed that either it did not come from the stomach or that some organ secreted no true gastric juice.

The physical examination revealed no abnormality in the lungs, heart, or abdominal organs. Posteriorly over the chest in the left infrascapular region a small area of dulness was discovered. Over this there existed an absence of the respiratory murmur. Urinary examina-
tion showed nothing abnormal. By clapotement a loud splashing sound was heard over the epigastrium, so that gastrectasis seemed possible. On auscultation over the esophagus during the act of swallowing the deglutition murmur was not audible.

Ewald's test breakfast was given, and an hour afterward the stomach tube was passed. To the author's surprise, it did not enter the stomach, but at a distance of fifteen inches and three quarters it met an obstruction. Nevertheless, nearly one pint of fluid and food was withdrawn, which seemed to contain the ingredients of the test breakfast, and also a piece of coagulated egg albumin which the patient asserted that he had ingested the day before. Clearly it seemed that a diverticulum existed immediately above the diaphragm. One peculiarity seemed important—viz., that while the rigid bougie could pass into the stomach, the soft, flexible tube could not be induced to enter. More experiments with the bougie demonstrated that at times it seemed to meet with some obstruction, at other times it would enter the stomach. The author was unable to procure a rigid stomach tube, consequently after many trials he gave up the attempt to introduce the soft-rubber tube into the stomach. After each meal nearly one pint of fluid could be emptied from the sac. After emptying the sac, the dullness in the left infra-epigastric region constantly disappeared.

The patient was given a soft-rubber stomach tube and instructed to introduce it and empty the diverticulum after each meal. A few days afterward he returned with the surprising information that he had pushed the tube into his stomach, and to demonstrate it, after several failures he finally pushed the tube to twenty inches and a half. Some contents were immediately expressed. Hydrochloric acid by Boas's test presented a marked reaction; the biuret reaction showed the presence of peptones, and pepisin was also demonstrated. This was in marked contrast to the many examinations which had never shown either hydrochloric acid, pepisin, or albumoses.

A great many other tests were made. A capsule of potassium iodide was swallowed on an empty sac. Twenty-five minutes later no trace could be found in the saliva by nitric acid and starch paper. One dram each of tartaric acid and bicarbonate of sodium ingested in solution separately did not distend the stomach, but repeated eructations ensued. It was obvious that it entered the sac, the orifice of which was too large to prevent the escape of the carbon dioxide formed.

These examinations very clearly demonstrated the existence of a pulsion diverticulum of the esophagus situated immediately above the diaphragm. Its size was larger than any of which the author was able to find a record; it held about fourteen ounces. Diverticula at this location are very rare, according to Zenker.

Prognosis seemed rather unfavorable. The danger lay in the possibility of ulceration and subsequent perforation, and in the continued enlargement of the sac with a consequent complete stenosis of the gullet. Food entered this dilatation first, which, becoming full, pressed on the sides of the esophagus, thus occluding the lumen below the mouth of the sac. This last-mentioned danger is almost sure to arise in time. Surgical intervention, on account of the peculiar location, being surrounded by important structures, seemed impossible, and in consultation Professor Tuholske advised against an operation.

The treatment consisted in evacuating the sac with the stomach tube after each meal. Thus the patient ceased to regurgitate food in the interval between meals and at night and felt very well.

A few months later he presented himself one evening, saying that he had visited Schrader, the healer, in Illinois, and felt so much stimulated that he ate his supper without much distress, and believed himself healed. A few days later he acknowledged that he was still the same.

Three years have elapsed. The condition is about the same.

“Old Maids’ Insanity.”—Mr. W. J. Handfield Haslett (Treatment, June 8th), in an interesting paper on Some Climacteric Neuroses, read before the Thames Valley Branch of the British Medical Association, says:

“There is another variety of climacteric disease which is purely mental, of slow development, and very incurable. For want of a better name, it is called ‘old maids’ insanity.’ This variety is not very common, and I have only had three cases under my care. It occurs in single women who have led a severely strict and virtuous life, devoting themselves to religious and intellectual work, and carefully repressing the animal side of their nature. They are generally far from attractive, but this, I presume, is a coincidence. Just before the menopause sets in there seems to be a spurt of erotic excitement, and some unfortunate man, frequently a clergyman, becomes the victim of their attentions. One of my cases was a very typical one, and may be thus shortly described: The lady was forty-two, and lived a rather solitary and egotistical life in lodgings, being very much devoted to church matters. She was a member of the flock of an aged vicar, who was a very accessible man, and no doubt the lady saw a good deal of him. At any rate, she never missed an opportunity of seeing him, and he could never turn a street corner without running the chance of meeting her. Her whole life became dominated by one thought—the vicar. This doubtless arose from the fact that she had no other interests in life. Every word the vicar said to her and every glance from the pulpit was construed into a confession of devotion. She told all her friends of his undying love for her, and no doubt the vicar, hearing of it, was more embarrassed in meeting her, and this added to the confession of his attachment. The poor old vicar’s life was a misery to him. But it did not end here. Insane suspicions began to arise; she believed the vicar had bribed the doctors to give her medicine which affected her sexual health, and she described to me how the drugs they gave her turned the lower part of her body green. Then the inevitable jealousy arose, and another woman became the object of her insane dislike. At last matters reached a climax. One Sunday in church she rose up and accused the other lady of trying to estrange the vicar’s affections from her, and ended by chasing her rival around the aisles with the family umbrella. This was too much; she was certified next day and sent to an asylum. This all happened some years ago. The lady still has her delusions, although they have faded considerably and are less in evidence; still, they are there all the same. There is much moral perversion. The patient is a masturbator, and puts a meretricious construction on the most innocent action of her friends. She has made self-indulgence a fine art, is indolent and selfish, yet withal deeply religious. These cases act as a warning that severe repression of the animal instincts often has
beneathful results. In the words of Horace, 'Naturam expellas furca tamen usque recurrit.' Such women are social terrors. They bring grave accusations against innocent people, they are often dangerous through their insane suspicions, and the only treatment is to remove them once and for all from their old surroundings, and put them under proper care."

**Strontium Bromide in Epilepsy.**—Mr. Antony Roche, of Dublin, who has before written upon this subject, finds now (Lancet, April 22d), from numerous letters that he has received from members of the profession, that considerable interest has been excited, and that, while some of his correspondents have tried the system he has advocated with success, others apparently have failed to comprehend his former communications, or have expected results which he never suggested as possible. For example, he never supposed that the bromide of strontium would improve the mental condition of children suffering from fits in whom there was congenital malformation of the brain, or that it could benefit the mental faculties of persons who suffer from fits associated with advanced cerebral disease. The most to be expected in such cases from the bromide would be the lessening of the frequency of the attacks. Again, he never asserted, as some of his correspondents appear to think, that the bromide was invariably successful in all cases of even so-called idiopathic epilepsy, or that the drug had simply to be poured in without any other treatment or regulation of habits, diet, etc., to be successful. It is a very elementary consideration in the treatment of epilepsy, as indeed in that of all diseases, he remarks, that each individual case must be studied and treated for success in the treatment given by one medical man, as compared with another, depends mostly upon the care and thoroughness with which it is carried out. For example, in each case of epilepsy beginning in adult life, whether any predisposing or exciting cause can be detected or not, infection by syphilis should always be borne in mind, and Jacksonian attacks should excite suspicion; even when the form is the ordinary one, syphilis may be the cause, as he knows from experience. In such cases he gives the iodide of strontium with the bromide. He finds the strontium iodide more efficient and less depressing than the potassium salt. For some years he has used strontium iodide not only in these cases, but also in rheumatism, asthma, etc., in place of the potassium iodide, and thinks it is more easily taken.

He has frequently given three draffms a day for weeks, and has never observed any symptoms of poisoning. The bromide rash is sometimes troublesome, but two minims and a half of liquor arsensicis in each of the two doses will generally control it, and this can be continued for about six weeks and then omitted for a short period. It appears to Mr. Roche that the bromide rash is more troublesome in fair-haired people with thin skins than in dark, thick-skinned people. In addition to the bottle containing the regular daily doses, he orders another, called for convenience the intermediate. This contains twenty grains to each half ounce, and he directs the patient, should he have any aura, to take a tablespoonful of it every half hour until the sensation passes off. Most of his patients assure him they have thus averted the pending attacks. If the patient finds no inconvenience from the bromide except the rash, he should continue its use for an indefinite period. To the proposition to stop the medicine if there has been no return for a year the author does not agree. It is desirable in each case, he says, to find the smallest dose that will effect the purpose, and to continue it. There are just two precautions he would mention: Be careful that the medicine is pure and, secondly, be careful that the apothecary does not substitute the potassium salt for the strontium, if he does not happen to have the latter at hand.

Mr. Roche has never met with a case carefully investigated and persistently treated in which the number of the attacks was not materially diminished, and he has many cases in which there has been no return of the attacks at all, even after an interval of four years, the patients, of course, continuing the use of the medicine.

A "Noncombatant" in Action.—We are glad to quote from the British Medical Journal for June 17th the following: In his report of the recent action in Samoa, where both British and American naval officers were killed, Captain White, of the Philadelphia, speaks as follows concerning the conduct of Passed Assistant Surgeon G. A. Lung, United States Navy: "At times when the fire from the concealed natives was thickest, and at all times by his example, he encouraged the young and inexperienced men to the proper performance of their duty. On the completion of the work of his profession, he assumed command of our blue-jackets, and marched them to the United States consulate."

**The Treatment of Salpingitis.**—Mr. J. W. Taylor, F. R. C. S. (British Medical Journal, May 20th), at a recent meeting of the British Gynaecological Society, read a paper on this subject, in the course of which he laid down the following propositions: 1. That a large number of women who are suffering from tubal disease have been at some time or another exposed to the infection of syphilis as well as of gonorrhea; that these undoubtedly show marked improvement after a prolonged course of mercury and iodides, and in the course of this treatment, unless acute pyosalpinx intervenes (in which case medicine is useless), it is the rule rather than the exception for all gross physical signs of disease to slowly and permanently disappear. 2. That many cases in which there is no history of syphilis, including cases in which there is the unmistakable history of gonorrhea, pure and simple, as the sole cause and starting point of tubal disease, do similarly improve and get permanently well under the same course of treatment, provided always that the disease stops short of acute pyosalpinx and its dangerous complications. 3. That acute pyosalpinx is peculiarly liable to occur, in the first place, on the left side of the body, and its special severity is probably due to secondary infection from the rectum. That such cases, whenever possible, should be treated by free incision of the posterior vaginal fornix, by thorough exploration and emptying of all pus cavi ties from the pouch of Douglas, and by iodoform-gauze drainage. That this is far preferable to the older operation of removal of the appendages, which is not only much more dangerous, but is peculiarly liable to be followed by fecal fistula, an operation sequel sometimes worse than death itself. 4. That such cases of mixed infection and acute suppuration, treated by operative evacuation of the pus, with or without removal of the appendages, do sometimes not only recover, but remain permanently well without further treatment, the auten ness of the inflammation appearing to terminate the process of infection. In other cases the recovery is not
so complete, relapses are met with, and these cases should be followed up by a course of specific treatment, the beneficial result of this being often immediately manifest when the wound tissues are unhealthy and the healing is delayed. 5. That occlusion of the tubes and peritubal adhesions consequent on gonorrhoeal salpingitis have no direct specific causation, and must be regarded rather as secondary mechanical results of the local peritonitis, which has been caused by salpingitis. Their absorption and disappearance will not therefore be secured by the cure of the gonorrhoea, and sterility may persist, although gonorrhoea may be entirely eradicated from the system. 6. That in gonorrhoea of the pelvis there will probably remain a residuum of intractable cases, particularly cases of complication with other diseases, such as fibroids of the uterus. That in these cases operative removal of the organs affected will still be required, and that vaginal hysterectomy, whenever possible, with or without removal of the appendages, is not only the most rational operation in theory, but is productive of the best final results.

The Expulsion of the Placenta after Childbirth.—Dr. R. G. Woodworth (Denver Medical Times, May) has used the following method with excellent results: After the delivery of the child he notes for a few minutes the contraction and relaxation of the uterus. After a repetition of this for a few times, and when he feels quite certain that there exists no immediate danger from haemorrhage, he begins the delivery of the placenta by bimanual pressure. To apply the pressure, take place beside the mother, press the finger tips down upon the abdomen (the right hand on the right side of womb, the left on the left) beneath the womb, so as almost completely to encircle the same by both hands, and then, not by pressing the womb down and backward against the spine, but by sustaining and supporting it, and, if need be, gently carrying it toward the vaginal outlet, begin to squeeze it, exerting firmer and firmer force until the appearance of the placenta and all coagula.

He is fully convinced that this is the ideal way. Pressure with one hand can accomplish nothing in a womb that is not able to take care of itself if sufficient time is allotted. Pressure with one hand has no sustaining power over the womb and only tends to drive it out of place. Pressure with traction on the cord simultaneously is a dangerous procedure, as the pressure is apt to be slight compared with the traction, and, as stated before, tends to displace the uterus. Traction exclusive of pressure is the most dangerous, as this is done with no reference to the contractions, and hence can only result in facilitating the occurrence of haemorrhage. These methods are quite likely to be followed by retention of portions of the secundine, and to expose the mother to the additional danger of puerperal fever. Bimanual pressure not only secures safety against retention of any portion of placenta, but also accomplishes the expulsion of all coagula.

The Microscopical Condition in a Case of Intermenstrual Pain (Mittelschmerz).—Dr. Augustus Addin- sell (Transactions of the Obstetrical Society of London, January and February), at a recent meeting of the society showed some microscopical sections, and gave a demonstration on the condition of the tube and ovary, removed by Mr. Bland Sutton for the relief of intermenstrual pain which had persisted for eight years. The pain had followed the birth of the last child; its chief characteristics were that it commenced twelve to fourteen days after the cessation of the period, was referred to the left ovarian region, increased in intensity for three days, and was usually but not always accompanied by the discharge of a clear watery fluid from the vagina. The uterus was acutely retroflexed, bound down by adhesions, and the left ovary was firmly impacted in the angle formed by the flexion. There was nothing of interest in the ovary, which was secl-osed and cystic. The tube was found to be closed at the abdominal end; the diameter of the lumen was somewhat increased. Microscopical examination failed to reveal either the gonococcus or tubercle bacillus. There was marked thinning of the walls, and evidence of oedema separating the muscle fibres. The ends of the places were clubbed; small-celled infiltration was consid-erable in the connective-tissue stroma of the pipe, and in the subepithelial connective tissue of the tube wall. The epithelial cells were in a condition of cloudy swelling; the cell walls were ill-defined and the nuclei undergoing alteration. Cell proliferation was very marked, and in many places there was a heaping up into clusters and bunches of epithelial cells. This was the first occas-ion upon which the pathological histology of the tube had been demonstrated in connection with intermenstrual pain. The closure of the uterine end, and also of the abdominal ostium, would convert the tube into a retention cyst and produce hydrosalpinx. In this case, however, the abdominal ostium alone being closed, the increased secretion of fluid, due to the marked prolifer-ation of epithelial cells, would naturally pass in the di-rection of least resistance—namely, through the patent uterine end into the uterus, whence it would be expelled into the vagina.

Proceedings of Societies.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Meeting of May 3, 1899.

The President, Dr. S. Alexander, in the Chair.

Otitis Media; Cerebral Abscess.—Dr. Charles Phelps reported a case of cerebral abscess having its origin in an otitis media. It was of interest because of certain points in the diagnosis. The patient was a young man of twenty-five years, who had had otitis media for a considerable time, but had been otherwise in good health. During a copious discharge of pus from the ear he had been taken very suddenly ill, and had lost consciousness almost immediately. He had seen this patient with his attending physician at Melrose, Dr. Henschel, and the diagnosis had been meningitis from infection through the petrous portion of the tem-poral bone. The mastoid cells and the sinuses had not seemed to be involved. After a time symptoms which were attributed to cerebral abscess developed. Among these was descending neuritis. Dr. Phelps trephined over the ear, and found nothing except that it was possi-ble to establish a connection between the point of treph-ining and the auditory passages. There being no further guide to the situation of the abscess, operative,
measures were abandoned. The man lived for nearly four weeks. At the autopsy it was ascertained that there had been an acute purulent meningitis involving the lower surface of the cerebellum and the anterior surface of thepons, and extending into the spinal canal, and that the path of infection had apparently been through the choroid plexus into the opposite lateral ventricle, namely, the left, which was filled with pus. The case seemed to him to be rather unusual from the fact that the infection had been through the roof of the petrous portion instead of through the mastoid region, and that the abscess had formed on the opposite side of the brain in the ventricle.

A Review of a Trial for Murder Involving a Study of Pistol-shot Wounds of the Head.—Dr. Charles Phelps read a paper with this title. Dr. Reginald H. Sayre said that the discrepancy regarding the statements made concerning the carbon deposit in the tissues might be explained by the fact that in the discharge of powder from short barrels the powder was not wholly consumed, and hence the carbon might be found in the tissues.

A Malignant Periosteal Tumor.—Dr. R. H. Sayre exhibited a specimen of this kind that had been taken from a girl, thirteen years of age, who had been in good health up to last August. At that time she had fallen and injured the knee, and had been confined to bed for a few days in consequence. After a short time she had begun to suffer from pain in the knee. When first seen by him, in March of the present year, the knee was quite swollen, and from the general appearance of the child he suspected the growth to be malignant rather than tuberculous, but, on the supposition that it might possibly be tuberculous, an effort was made to save the joint. This failed, and ten days ago he had operated upon her. On cutting into the mass he had found a large bleeding tumor, and had consequently amputated at the hip joint by the Fourneau-Jordan method. On opening the knee a large blood-clot was found in it. The growth had spread out quite suddenly from the cartilage, but had not involved it. He had controlled the hemorrhage by Richards’s artery compressor—a band passing across the pelvis and having a knob pressing down on the vessels and actuated by a screw.

Dr. W. R. Townsend said that he had seen three or four cases of osteosarcoma of the lower end of the femur, and had been inclined at first to look upon the condition as tuberculous instead of malignant. He recalled one case which had been watched by others as well as by himself for nearly eight months before the tumor had developed to an appreciable size above the knee joint. In one of his cases there had been heat, swelling, sensitiveness, and pain, without any tumor above the knee, in the early stage, and in addition there had been some elevation of temperature, so that there had been every reason for supposing the case to be one of ordinary inflammatory joint disease.

Dr. Parker Syms spoke of a case in which he had had a similar experience regarding the diagnosis. The symptoms had all pointed to tuberculous of the knee. There had been some elevation of temperature also. The diagnosis could only have been made by an exploratory operation.

Dr. Sayre said that his patient had had a temperature between 99.5° and 101.5° F., and there had been local heat and distinct spots of tenderness. Consequently it had been taken to be a case of synovitis that had developed, but the subsequent history had shown that what had been supposed to be synovial fluid had really been a clot of blood. In this case the disturbance had been at first rather in the femur than in the joint, and this had led him to think that it might be a tuberculous focus which had not yet broken into the joint. In another case of osteosarcoma the tumor had developed shortly after pregnancy, and there had been a history such as one usually got in a case of septic synovitis of the knee. When he saw it, and operated, there was extensive malignant disease, but in spite of this the amputation was successful, for, five years later, the woman was reported to him as still alive and well.

A natural question arises in the mind when a new text-book appears on one of the well-founded sciences, “Why was it written?” An answer to the question in this instance is found in the preface: “The authors have long felt the need of a text-book which, while presenting the essential facts of human structure, judiciously avoids the unimportant and exceptional. They believe that the students in medical schools should neither be encouraged to depend upon pocket manuals nor be compelled to resort to encyclopedias.”

The amount of condensation allowable in an anatomical text-book of course differs with the judgment of the individual. It should not be carried so far as to make the work a bare statement of facts, which are in any case dry enough to the average student.

There is also the danger of setting too low a standard for the student, since he is adaptable, and the more is required of him the more he will acquire.

Gerrish’s anatomy strikes a very happy middle course; while in some things it is not so full as the larger anatomies, in others it most favorably compares with them and avoids prolixity.

The volume reminds one forcibly of the familiar Gray in regard to size of page, type, and arrangement of subjects.

The articles on the bones, joints, and veins have been written by Professor George Woolsey, of Cornell University Medical College; those on the peripheral nervous system, the eye, the nose, and the skin, by Professor W. Keiller, of the University of Texas; that on embryology, by Professor J. P. McMurrich, of the University of Michigan; that on the arteries, by Professor A. D. Bevan, of Rush Medical College, Chicago; that on the reproductive organs, by Professor G. D. Stewart, of the University and Bellevue Hospital Medical College; and the remainder by Professor Gerrish.

There is an introductory chapter on the elementary tissues, followed by a very excellent but brief chapter on human embryology. The articles on the bones and joints are the masterpieces of the book and surpass, in
our opinion, those on the same subjects found in most other text-books.

A feature of the book is the illustrating of the article on the muscles. Every important muscle is outlined by itself in color on the outline of the skeleton, in addition to figures of the muscle groups which are taken from Testut.

We are sorry to see the schematic way of describing the relations of the arteries adopted; the old formula skin, superficial fascia, etc.

The description of the central nervous system is short but clear, and, although some things are omitted which it seems to us ought to have been included, is on the whole excellent.

The articles on the thoracic and abdominal cavities and their contents are too abbreviated. The description of the peritoneum is very short, and no student could understand it from its purport. A concession is made in giving the names of some of the peritoneal ligaments, but a knowledge of these is not a knowledge of the peritoneum.

No mention is made of a second duct in the pancreas, the duct of Santorini; yet this has an important clinical bearing. A few errors appear, although slight, such, for instance, as the statement that the right bronchus is more horizontal than the left.

Passing over the articles on the generative and urinary organs, which are very good, we come to the chapter on relational anatomy, on which special stress is laid in the preface. We are unable to say that this chapter comes up to our expectations. It is divided into three parts, dealing respectively with plane sections, surface anatomy, and normal Röntgen pictures. Very little text is employed, entire reliance being placed on the figures.

The sections are modified from Braune, and in the thoracic region show a position for the esophagus which is not generally accepted. We question the value of sections of the extremities for purposes of teaching; as a rule they do not convey much to the student’s mind.

The chapter on surface anatomy consists entirely of figures from photographs with explanatory diagrams. The Röntgen pictures are very good, but their value is questionable.

The nomenclature used can hardly be said to conform to any fixed system. A number of the newer terms are employed, the synonyms also being given. We notice the terms dorsal, posterior, and hind used indiscriminately to designate the same relation. The term hind we think is new in this sense and even more ambiguous than posterior, insomuch as it implies a caudal rather than a dorsal relation.

The illustrations throughout are very good. Most of the engravings are taken from Testut’s Traité de l’anatomie, while numerous diagrams are inserted.

On the whole, the book is very pleasing and, considering its aim, namely, to be a middle ground between the more complete text-books and the compendia, it is eminently successful.

Without wishing to detract in the least from the reputation of any one else in this special field of literature, it may safely be said that since the death of Sir Morell Mackenzie Mr. Lennox Browne has been a foremost representative of English specialization in diseases of the nose and throat. His many years of laborious work at the Central London Hospital and his valuable contributions to the literature of his chosen field have gained for him an enduring reputation in this department of medical science. His life work is epitomized in the fine volume now presented to the profession. While it is confessedly designed for the general practitioner, it will find its most generous and discriminating critics among the author’s colleagues the world over.

The first three chapters are devoted to the anatomy and physiology of the larynx, pharynx, and nose. Next come chapters on methods of examination, general semiology, and therapeutics. It is agreeable to note the prominence given under the latter head to hygienic and dietetic measures. Then are taken up in logical order the various diseases of the areas under consideration. Special mention may be made of that portion covering the subject of bacteriological etiology. Under diseases of the larynx is included a chapter on diphtheria of which mention is made below. The closing chapter is entitled Aural Maladies associated with Nasopharyngeal Diseases. Finally come an elaborate formula for remedies, fifteen colored plates, indexes, etc.

Space does not permit us to do more than allude to but a few of the many interesting questions which Mr. Lennox Browne discusses. No man can have done the vast amount of work he has without his records containing much that is invaluable with reference to the practical management of disease. Moreover, the author brings to his task the experience of years of general work in medicine and surgery. All the more worthy of the most careful consideration, therefore, are his special studies laid down on this broad foundation.

Mention may be made, however, of one or two topics. The author considers it incumbent on us to consider seriously the necessity of a new classification of tonsillar inflammations. We must abolish the classification based solely on the clinical aspects of the disease. The efforts of some authorities to harmonize the bacteriological with the histological evidence as a basis for classification are too complicated for practical application. Efforts to make the basis purely a bacteriological one have not thus far been convincing, from the facts that all mouths contain streptococci and that in disease more than one organism is almost invariably present. No solution of the problem is offered, the author agreeing that it must be left to the future.

The chapter on diphtheria will be read with much interest. It is a concise exposition of the subject and for clinical purposes covers all points fully. The author’s views on antitoxine may seem to American readers a bit strange. His attitude toward antitoxine is not by any means one of absolute opposition, but he does not share the enthusiasm of most of the American writers on pediatrics. He does not consider that statistics have thus far proved the positive value of this new remedy.
No allusion is made in the text to the noteworthy collective investigations of the American Pediatric Society, which in this country at least have gone so far toward overcoming opposition. In common with some other writers on diphtheria, the author believes that the major share of the advantage of the serum treatment lies in the dynamic properties of the blood serum itself rather than in its antitoxic constituent.

The chapter on laryngeal tuberculosis is complete and well illustrated. Adherence is given to the surgical methods of Krause and Heryng, which in the author's hands have led to some brilliant results.

Under the heading of malignant neoplasms of the larynx, Mr. Browne deprecates the attempt at removal by means of endolaryngeal intervention of an undoubted sarcomatous or epitheliomatous growth per vias naturales, and he does not approve of the use of the galvano-cautery below the level of the epiglottis. Concerning laryngectomy, partial and complete, he occupies a middle position, realizing that statistics are continually showing improvement, but feeling that greater discrimination should be exercised in the selection of cases for operation.

Concerning the general make-up of the work little need be said. It is in every way a model volume. The colored illustrations of the pathological conditions which are so freely scattered through the text are clear and distinct. The large plates in the back of the volume have been drawn from life by the author himself. They are double-paged, the left side being left blank so that when they are unfolded the entire plate is open to the reader's eye and he is not obliged to keep turning from text to plate. It is a pity that this simple but effective device is not followed in all works of this kind. The book has a flexible back, so that it easily lies open on the desk.

Finally, it can not but be pleasing to the American colleagues of Mr. Browne to note that throughout the entire volume, from preface to index, their work receives at his hand the most generous recognition and unstinted praise.

"When I was asked to write a book upon the balneological and gymnastic treatment of heart disease," says the author, in the preface, "I suggested to the publishers that a wider scope should be given to the work, in order that the place and influence of these measures might be determined by some consideration of the character and general treatment of the conditions they were designed to rectify. To this they readily assented, with the result that I have written the sections which precede an account of the measures in question."

The sections alluded to are indeed an admirable addition, and it is difficult to see how a proper understanding of the treatment by bathing and exercise can be had without the introduction thus provided. That the physical examination of the heart, which subject occupies the first three chapters, is no novelty is true, but the propriety of the inclusion is self-evident, and as Dr. Morison presents it, it is worthy of thoughtful study. The fourth and fifth chapters discuss the extracardiac signs and symptoms of a failing heart. Then are ably considered the factors that operate in cardiac disease to determine the treatment and the outcome, and these are sufficiently well described by the adjectives neurovascular and hemic. A brief chapter presents the "general" treatment of cardiac failure, by which is meant the ordinarily employed drug and hygienic means, and then we are introduced to the essence of the book, which may best be described as a careful and able examination and presentation of what is known as the Nauheim treatment.

Too much can scarcely be said in favor of this treatise. The author has studied carefully and thought clearly, and has made every effort to be thorough and just. His conclusions may not invariably meet with agreement, but he is far from intolerant in their formation, and, indeed, as everybody knows, the rationale of the Nauheim treatment is scarcely susceptible of complete solution. The author has observed the treatment at Nauheim and has been afforded every opportunity for its study both by Schott and by Heineman. He has used the methods of the "Kur" in practice at home, and his presentation of the subject is therefore doubly valuable and interesting to us. That the treatment is of great value few will deny, but it is unfortunate that it should not be better understood by Americans. Latterly there has indeed been an awakening of interest in Nauheim, and we can think of no work better calculated to further this interest and to satisfy the reader than this one.

The titular name, Cardiac Failure, is incontestably correct, but conveys rather the idea of syncope than of a "failing" heart or a failing compensation, which after all is the thought that is intended. In this way the title might perhaps be misunderstood.

An admirable summary of the treatment is given by Dr. Groedel, of Bad Nauheim, in a brief appendix.

The character and scope of this little book are sufficiently described in its title, and for the rest it remains only to say that it is an admirable condensation and presentation of recent medico-legal decisions. To the physician and the lawyer alike it will be of interest and no doubt of service. It is to be hoped that there may be further issues of the work as material accumulates.

Railway surgery is to some extent a specialty in the eyes of many members of the medical profession in this country; it has its own societies and its own periodicals. It is not to be doubted, therefore, that Dr. Herrick's work will find many interested readers. If we find it somewhat disappointing, it is largely owing...
to the fact that the profusion of its illustrations encroaches upon the text rather unduly.

It should be explained that this volume is a new and amplified edition of Dr. Dowee's well-known work, Lectures on Massage and Electricity in the Treatment of Disease. The reason for the change of title is not apparent to us, for the one formerly used was admirably descriptive. Of the new work it suffices to say that in it the subjects of massage and medical electricity are well and thoroughly presented. The work of the publisher, we regret to say, is crude.

The author of this little pamphlet has endeavored to explain the position of woman in the past and to prophesy her position in the future by invoking the well-known laws of physiology and anatomy to assist him. In doing so he may have been able to come to a very satisfactory judgment from a masculine point of view, but has laid himself open to the accusation from the feminine side of a lack of gallantry, and, furthermore, to the charge that his writings on the subject are somewhat fanciful. The substance of his contention is that women are best in their homes and are not suited for an active public life.

A NASAL ENCHONDROMATOME.

By HERMAN L. ARMSTRONG, M. D., BROOKLYN.

The instrument—a cut of which is here given—will, I think, doubtless prove a valuable addition to the armamentarium of surgeons who are operating frequently within the nasal lumen for the restoration of the normal function of the nose. Especially will this instrument prove valuable in those cases where it is
The Treatment of Fibrous Stricture of the Rectum.

—Dr. W. H. Horrocks (British Medical Journal, June 3d) says that the usual treatment by passing bougies is very painful and affords only temporary relief. Forceful dilatation is a dangerous and unscientific method. It is dangerous because the stricture yields at its weakest part, which may lead to laceration and infection of the peritoneum. It is unscientific, as the tear, when healed, leaves the patient in much the same condition as before the operation.

He then records one or two cases treated very successfully by a vertical division at the part most removed from the peritoneum. The vertical is converted into a transverse slit, and the margins stitched together. To do this, the stricture must be within reach, and it is an advantage if the mucus membrane above the strictured part is loose and healthy.

He says: The simplicity of this method, which is an application of the operation of pyloroplasty to rectal strictures, is a great advantage in treating suitable cases. There seems no reason to doubt the permanency of the cure.

Climate in the Treatment of Tuberculosis.—Sir Hermann Weber (British Medical Journal, June 3d), in a paper read before the International Tuberculosis Congress in Berlin, says that ocean voyages are not rarely recommended because the following characteristics are attributed to the sea: (1) Purity of the air; (2) slight range of temperature; (3) abundance of light; (4) constant movement of the air; and (5) mental rest. However, if one examines the conditions of an ocean voyage more exactly, one finds that these advantages are not always completely present. For instance, the purity of the air is limited almost entirely to the deck, and is generally wanting in the sleeping cabins and the saloons; the pleasant movement of the air is often transformed into a violent storm, while in the zones of calm the reverse is the case; the temperature does not vary much from day to day, but on a long sea voyage the oppressive heat of the tropics has to be supported. Hence the treatment of a serious illness on a sea voyage is rendered difficult by the bad air of the small cabins. In respect of the choice between different voyages, he mentions that, to obtain the full effect, one of the longer voyages must be selected, one which lasts about six to sixteen weeks, without including the time spent on land between the voyage out and the voyage home. The best for patients are the voyages to Australia and New Zealand around the Cape of Good Hope (not Cape Horn, on account of the great cold), and that to the Cape of Good Hope itself, which in suitable cases may be combined with a stay of several months on the highlands of South Africa.

Of his observations on the influence of sea voyages in pulmonary tuberculosis, which lasted from six weeks to seven months, he notes in seventy cases there were thirty-four showing improvement, eighteen showing little change, and eighteen showing deterioration. The great majority of the cases were in the first or commencement of the second stage; only seven were in the third stage.

From what he has observed he would give it as his opinion that sea voyages can do good service in a certain number of tuberculous cases, but that in most such cases other climatic and hygienic methods of treatment exercise at least just as good an influence. If, however, persons of strong constitution, who like sea voyages, develop phthisis under the influence of overwork or mental worry, long sea voyages are to be preferred to all other methods of treatment. A decided advantage of sea voyages is that patients are much more protected from excesses than at many well-known health resorts. Permanent weakness of constitution, very decided tendency to seasickness, unalterable dislike of monotonous diet constitute contraindications.

It would be an advantage, he says, if there were well-arranged medical ships, a kind of "sea sanatorium," both for long voyages and for short ones—for instance, in the Mediterranean and to the West Indies during winter, and in the North Sea during summer; but this would be hard to arrange without great cost to the patients. Sea voyages can be recommended for prophylactic use against scarifolia and also against tuberculosis. Among sailors and seafaring persons there is less phthisis than among soldiers of the same age on land. Out of eighteen boys of very tuberculous families, whom the author advised to enter the navy, only two became con-
sumptive, whereas among their brothers and sisters who chose learned, mercantile, or sedentary occupations, the number of deaths from phthisis was at least three times as great.

The author gives the following brief indications for the use of different climates in different cases of tuberculosis: 1. First of all, we must be clear as to whether we have to do with a strong or a weak constitution. If the patient belongs to a long-lived family, we may suppose that he possesses a strong constitution, even if other members of his family have died of tuberculosis. If he belongs to a short-lived family, we generally have to deal with an originally weak constitution, even if no member of his family has died of tuberculosis. Another hereditary tendency, which points to a considerable power of resistance, is that toward gout, which to a certain extent is antagonistic to tuberculosis. Further, those persons who from youth up always feel better, are more energetic, can eat better, and put on weight in warm weather, but in cold weather become less capable of work, generally belong to the class of weak constitutions, whereas those who have always done better in the cold possess stronger constitutions. Patients who from childhood onward have always had high fever with every slight illness, and have recovered with difficulty, and who always have moist hands, must generally be reckoned among the weak, creptic constitutions—a conclusion which is mostly confirmed by the color of the skin and mucous membranes, the general appearance, and the weak and irritate action of the heart. If we have come to the conclusion that the patient has a weak constitution, we must be guarded in recommending great altitudes and long sea voyages, and give the preference to warm, sunny, and sheltered places. On the other hand, in strong, somewhat torpid constitutions mountain climates are to be avoided, and occasionally also long sea voyages. In these cases one can do much by keeping them continuously in the open air, by good feeding, and by regulated exercise.

In regard to the following indications the constitution always has to be considered:

2. In cases with limited disease at one or both apices, without or with an only slight amount of fever, nearly all climates can be made use of, but especially great altitudes and sea voyages if the constitution is a strong one.

3. Cases with limited local disease and high fever must be at first treated in their houses or in the neighborhood of their homes.

4. Cases with extensive disease of one lung or of both lungs, without fever or with only slight fever, are more difficult to advise. In the majority of these cases treatment at an only moderate elevation, or at warm seaside localities, deserves the preference.

5. In advanced disease with fever, long journeys should be avoided, and, if possible, neighboring sheltered health resorts, together with careful supervision, should be recommended.

6. In progressive tuberculosis with scattered foci in both lungs and much fever, sheltered localities near the patient's home, or the home itself, are probably the best places.

7. In cases of chronic, slowly progressive phthisis, the author has seen, on the whole, better results from warm winter resorts, and sometimes from sea voyages.

8. Quiescent cases with extensive damage or cicatrization are generally better off at only slight elevations.

9. Cases with albuminuria without fever should avoid great altitudes, and select dry places.

10. The complication of moderate diabetes does not exclude the use of great altitudes, but the latter are injurious in cases with advanced diabetes and emaciation. Similarly, great altitudes should be avoided in cases where the tuberculosis is secondary and the diabetes the primary affection.

11. Chronic cases with much catarrh require places with as little wind as possible, but in the case of young persons places of great elevation with little wind need not be excluded, and are often even to be preferred.

12. Great altitudes are contraindicated in chronic cases with extensive emphysema; these cases require warm winter resorts or places with pine woods.

13. When asthma is a complication, in persons whose idiosyncrasies in regard to localities are unknown, no certainty in the choice of climates is possible; but in the majority of relatively young persons great elevations should be preferred, while in older persons moderately warm localities at only slight elevations should be selected or places amid pine woods.

14. In all climates for the treatment of tuberculosis selection of the dwelling house is of great importance; it should get much sun, should be sheltered from winds and free from dust, and should be built on dry ground; it should be removed from stagnant water and swamps, and from the impure air of factories and similar drawbacks.

15. For the prevention of scrofula and tuberculosis all healthy climates can be used, as long as a good diet and plenty of time in the open air can be obtained; but great altitudes and marine climates have advantages—the former rather against pulmonary tuberculosis, the latter (including sea voyages) more against scrofula.

16. The cure of tuberculosis during the early stages is possible in all healthy climates; some climates, however, have advantages for various cases over the other climates; for instance, notably those of great altitude. But climate by itself without careful medical supervision is generally insufficient. The patient's blind reliance on the climate often leads to errors, to aggravation of the disease, and to death. For the majority of patients, therefore, treatment in sanatoria should be preferred, but for the treatment of the poor it is a necessity. The erection of numerous sanatoria for the people is therefore a national requirement for the cure, the prevention, and extermination of tuberculosis.

The Toothache of Hunger.—Practical Medicine for June, quoting the Maryland Medical Journal, says that in some persons hunger will excite markedly disagreeable sensations in the teeth. A case is published of a gentleman who, while convalescing from typhoid fever, was seriously annoyed by painful sensations in two of his molars whenever he became hungry. The pain was sufficient to arouse him from sleep, and could not be allayed except by the introduction of food into the stomach, when instant relief followed.

A Hospital's Responsibility for a Nurse's Negligence.—The Dominion Medical Monthly for June states that some time ago a woman went to a Canadian hospital to have an operation performed. She was put under ether, and when she regained consciousness after the operation she complained of pain in one leg. It was found that a hot-water bottle was lying on the leg and
had caused injuries which, it was asserted, resulted in permanent disability. The patient sued the hospital for thirty thousand dollars damages. At the trial term the complaint was dismissed, the judge affirming that the hospital authorities could not be held responsible. The case was appealed, and now the appellate division has handed down a decision that the hospital can not escape responsibility in that way, and a new trial has been ordered.

Schoolgirls and Corsets.—According to the Dominion Medical Monthly for June, the Saxon Minister of Education has recently issued a decree forbidding girls attending public schools in Dresden to wear corsets.

Newspaper Ethics.—The Cleveland Journal of Medicine for June says that W. A. France, one of the notorious advertising irregular "doctors" of Columbus, was arrested on a charge of practising medicine without first securing a license from the State board. The board was successful in obtaining a conviction on May 8th, and a fine was imposed of two hundred dollars. The newspapers of Columbus, says the Journal, having been paid large sums by the said France for advertising, refused point-blank to publish the fact of the trial and conviction. As the Journal comments, this is a fine commentary indeed upon the mortality of the daily press. The item was not sent out by the Associated Press. Nothing could better demonstrate the power of money to buy the newspapers, or the hold which the quacks have upon the editors and publishers of lay journals.

Decline of the Plague in India.—According to recent issues of Indian medical journals, there is a progressive decline in the mortality from plague. The Indian Medical Record for May 31st reports a steady decrease in Bombay, and says that the figures justify a hope that Bombay will soon see the last of its third great plague epidemic. In Calcutta the Record says that the death-rate from plague for the week ending May 16th was fifty-six below the normal.

The "Covade" and Prolonged Rest after Accoucheement.—Dr. F. Monin (Journal des sciences médicales de Lille, May 27th), in support of his argument that a prolonged rest in bed after confinement is unnecessary, cites incidentally the curious custom of the "covade," said to be prevalent in Corsica. He quotes Diodorus Siculus as saying, "In Corsica it is the husband who takes to his bed, while the newly confined mother bides herself with the household duties." Witowski (Histoire des accouchements chez tous les peuples, folio 336), he says, describes this custom as existing in the Indies, in both Americas, in Spain, and in the south of France. The following lines are translated from the Lucinade:

"In France yet again, and among the Béarnais
And the country of Navarre, when a woman is confined
The wife it is gets up, while the husband goes to bed."

The Earth Odor.—The characteristic odor of overturned earth, according to Clarke Nuttall (Knowledge; Gazettta degli ospedali e delle cliniche, May 18th), is due to a micro-organism, the Cladothrix odorifera, which he has isolated and found to produce a substance with this characteristic earth odor during its culture.

The Advancement of the African Race.—A public meeting was announced to be held on Thursday evening, July 6th, at Mount Olivet Church, on behalf of the enterprise initiated by Dr. J. Albert Thorne, a colored graduate of Edinburgh University, for the temporal and spiritual advancement of the African race. The list of supporters contained many medical men, among whom may be mentioned Dr. Frank Hartley, Dr. E. D. Fisher, Dr. F. Ferguson, and Dr. W. L. Stowell. Dr. Thorne proposes to leave for Africa and labor among the people of his own race.

The Attendance at the Columbus Meeting of the American Medical Association.—According to the Columbus Medical Journal for June 13th, exactly 1,737 delegates registered for the Columbus meeting of the association. It is believed that fully five hundred other physicians were in the city who did not register. Counting the visiting ladies, physicians not members, and exhibitors, it is believed that thirty-five hundred people were in the city in attendance at the different sessions of the association.

Self-inflicted Injuries Diagnosed by the Röntgen Rays.—The Berlin special correspondent of the Lancet says in its issue for June 17th that a fresh proof of the practical utility of the Röntgen rays has been supplied by a case published by Oberstabsarzt Dr. Bachofen, of Wiesbaden. A soldier who alleged that he had been bitten by a horse was admitted into the military hospital with a swelling of the third finger, especially marked at the tip and extending to the back of the hand. A sinus developed after several weeks in the neighborhood of the joint between the first phalanx and the metacarpal bone, and the introduction of a probe showed the bone to be denuded of periosteum. The sinus healed up after being laid open and cauterized, but the swelling continued and the mobility of the finger was impaired. An examination of the hand by the Röntgen rays resulted in the discovery of five needles in the second and third interosseous spaces of the metacarpus. There was also a small, scarcely visible, sinus in the fold between the second and third fingers. On the following day the roentgen examination showed only four needles, the man having extricated one of them through the sinus. All the needles were removed by a large incision and the hand became quite normal. The man at first pretended that he did not know how the needles had come into his hand, but he afterward admitted that he had introduced them because the hand was painful and he expected relief from the escape of blood. He had evidently inflicted these injuries on himself in order to obtain his discharge from military service, not foreseeing that by the aid of the X rays his imposture would be detected.

The Thirteenth International Congress of Medicine.—We learn from the Lancet for June 17th that Sir William Mac Cormack has been elected an honorary president of the Thirteenth International Congress of Medicine to be held in Paris from August 2 to August 9, 1900.

The Canadian Medical Association will hold its annual meeting in Toronto on August 30th and 31st and September 1st.

A Woman Professor of Comparative Anatomy.—The Gazettta degli ospedali e delle cliniche for May 16th announces the appointment of Miss Rina Monti to the chair of comparative anatomy in the University of Pavia.
THE NEW YORK MEDICAL JOURNAL, July 15, 1899.

Original Communications.

THE NATURE OF THE XANTHOMATA.*

By S. Pollitzer, A. M., M. D.

Much as has been written on xanthoma, it must be admitted that our knowledge of the subject is greatly deficient. In fact, hardly any two authors seem to hold precisely the same views, not only on the pathology of the disease, but even on the nature of the anatomical changes underlying the process. For some the xanthoma cell is a modified connective-tissue cell; for others it is of endothelial origin; while still others regard it as a heterotopic fat cell. From a clinical point of view, too, there is no less diversity of opinion; while some regard the plane, the tuberose, and the diabetic forms as identical processes, others place diabetic xanthoma in a class by itself. Since Addison and Gull, in 1850, on finding the plane palpbral and the nodular forms associated in the same individual, classified them as simply different forms of the same pathological process, it has occurred to no one to question the correctness of their assumption. This is the more remarkable when one considers the very manifest clinical differences between xanthoma of the eyelids and generalized xanthoma. The nodules of generalized xanthoma are firm, round, elevated papules; the patches of eyelid xanthoma are hardly, if at all, raised above the level of the skin, and to the touch are not to be distinguished from the soft neighboring tissues. Eyelid xanthoma, once established, remains without change through life. Generalized xanthoma is always of limited duration. I am aware that this last statement is not in accord with the generally accepted belief. All are agreed, however, on the temporary character of xanthoma diabeticorum, and though common multiple xanthoma is of much longer duration than the diabetic, it also differs from eyelid xanthoma in that it ultimately disappears. I shall recur to this point later. Eyelid xanthoma is quite a common disease; multiple xanthoma is very rare. Probably every case of multiple xanthoma in civilized countries is seen by a physician; while the cases of eyelid xanthoma, especially in men, rarely come to our consulting rooms, though we meet them often enough incidentally. It is probably well within the limits to estimate the proportion of eyelid to generalized xanthoma as a hundred to one. If the eyelids were in such a preponderating degree the seat of predilection for xanthoma one would expect in every case of generalized xanthoma to find it a fortiori on the lids; but, as a matter of fact, in only a few of the cases of xanthoma multiplex have there been lesions on the eyelids, and in many of these the eyelid lesions have had a distinctly nodular character unlike that of common xanthoma palpebrarum. On these clinical grounds alone I should feel inclined to regard xanthoma of the eyelids and generalized xanthoma as wholly distinct diseases.

As to the clinical relations of xanthoma diabeticorum and xanthoma multiplex, I share the view of Besnier and others that the two processes are identical. The lesions themselves are in all respects identical, except that the papules in the diabetic form rest on an erythematosus base. But even this difference is not constant, as I pointed out four years ago in a published note on a case of multiple xanthoma, in which a patch of nodules about the knees had a distinct erythematous flush. Diabetic xanthoma commonly undergoes involution after a brief period, therein differing from non-diabetic multiple xanthoma, but this difference is merely one of degree. In one of the first cases recorded (Addison and Gull) it was noted that the lesions were rather less prominent a year after their appearance. Several cases of more or less complete disappearance of the nodules have since been recorded. My own case is of interest in this connection, and I may be permitted here to add an appendix to the notes published four years ago.

I saw the patient in July, 1891. His disease had appeared about four years before that time. The nodules were scattered over the soles, over the outer border of the feet, and over the tendo Achilles. There was an extensive group on the front of each knee, another on the back in the lower lumbar region, another around each olecranon, while on the hands there were several small groups and isolated nodules. I saw the man again in November, 1896, five years after my previous examination and nine years after the appearance of the disease. He informed me that the lesions began to disappear soon after I saw him, and that all except a small group on the right thumb and on the left great toe had entirely disappeared within three years—that is, after an extreme duration of seven years. During the past two years he has had several attacks of biliary colic. Last August there was a recurrence of about a dozen nodules on the arms and a few on the knees, near but not on the site of previous nodules. The nodules on the thumb and great toe, which had persisted since the beginning of the disease, had undergone a notable change. They were not half so prominent as when I had seen them six years ago and had lost their peculiar yellow color. They appeared as firm, round, slightly elevated nodules, indistinguishable in color from the surrounding skin.

While on the subject of the duration of xanthoma multiplex, I should like to ask whether any one of the distinguished dermatologists here present has ever seen a case of generalized xanthoma that has persisted for more than fifteen or twenty years. The eyelid xanthomas carry their lesions to the grave. What becomes of our cases of multiple xanthoma? I believe

---

* Read before the American Dermatological Association, May 5, 1897.

* British Journal of Dermatology, 1893.

† Gyn's Hospital Reports, 1850, case of Eliza Parachute.
that my case is typical; that if the patient is not carried off by some intercurrent disease the nodules of xanthoma ultimately disappear.

Finally, as to the value of glycosuria in differentiating the two forms of xanthoma, there is a fair number of cases recorded in which there was no sugar in the urine, though the lesions presented all the characters of the diabetic form.* On clinical grounds, therefore, we may conclude that there is no sufficient basis for a complete separation of the xanthoma diabeticorum from the common xanthoma multiplex. These conclusions, derived from clinical considerations, are, we shall presently see, entirely corroborated by the results of the histological examination.

In reviewing the histological work done by previous investigators, the great divergence in the structure described by different writers as xanthoma can not fail to impress itself upon us. It needs but a glance at such pictures as those presented by Waldeyer, Virchow, Lentzen and Knauss, and Touton to show that they were dealing either with entirely different pathological processes or, at least, with vastly different stages of the same process. In view of this consideration I resolved not to be content with the examination of one or two specimens, but to compare sections from as many cases as it was possible for me to obtain. The material that I have examined includes a total of thirteen cases of the various kinds of so-called xanthoma.

Five of these were xanthoma planum palpebrarum. For sections of two of these cases I am indebted to Dr. Emil Grunin; and one from the lower lid by Dr. Martin W. Ware. The two latter were typical examples of xanthoma localized on the eyelids. The plaques were of comparatively recent origin and appeared to be still growing. The specimens were carefully fixed in formalin, sublimate, or Flemming’s solution, and afforded ample material for the most detailed studies. The cases of xanthoma tuberosum multiplex include nodules from my own case referred to above fixed in alcohol or in Flemming; several dozen sections from Dr. Morrow’s case, a clinical account of which has been published;* a few sections from Dr. Jackson’s case † (for both of these cases I am indebted to the kindness of Dr. Fordyce); and a few sections from Dr. A. R. Robinson’s case ‡ of elbow xanthoma. The cases of xanthoma diabeticorum are a few sections from an unpublished case of Dr. Lustgarten’s; a few from an unpublished case of Dr. Elliot’s; a few from the case that Dr. Robinson published in the International Atlas for Rare Skin Diseases, and a few from an unpublished case of Dr. Robinson’s of xanthoma diabeticorum without glycosuria. To all these gentlemen I desire to extend here my thanks for their courtesy. These thirteen cases include all the clinical forms of xanthoma excepting xanthoma of internal organs and that rare form of plane xanthoma which occurs occasionally on the palms or on parts of the integument other than the eyelids.

It is not my intention to weary you with a detailed description of the histology in each of these cases. Let me say that there is in general a complete uniformity in the structure of the cases of eyelid xanthoma, in that of the cases of multiple xanthoma, and in that of the cases of diabetic xanthoma. Let me add further that a comparison of my specimens with the accounts published by most authors shows that I am dealing with the usual and ordinary forms of xanthoma. It will not be necessary, therefore, to enter extensively into a description of the histology of xanthoma, which has been so well described by previous writers. But I shall present only certain points that strike me as important.

To begin with xanthoma planum palpebrarum, the entire cutis in some cases is filled, from the thin sub-papillary layer to the subcutaneous layer of muscles, with the xanthomatous tissue. This fact, in connection with the absence of practically all clinical signs of a

---

* It may be of interest to refer to the case of Colombini's (Monatsh., xiv, p. 129), in which a typical xanthoma diabeticorum was associated with the presence of pentose in the urine.

* Journal of Cutaneous and Genito-urinary Diseases, vol. xi, 1891.

† Ibid., vol. viii, 1890.

‡ Ibid., vol. iii, 1885.
cutaneous tumor, conveys a suggestion that I think has escaped previous writers. When we consider how very marked an elevation of the surface a slight follicular or other infiltration in the cutis produces, that even so insignificant an aggregation of cells as those constituting a milium produces a palpable elevation of the surface, is it not a striking fact that so extensive a formation as that in xanthoma planum, which may fill the entire cutis, produces no more than a half millimetre elevation of the surface, or even no elevation at all? And does it not force the conclusion that in xanthoma planum we are not dealing with a new formation at all, but rather with the substitution of one kind of tissue for a preexisting, perhaps normal, kind—in other words, with a degeneration rather than with a neoplasm? Allow me to present here a photomicrograph showing a typical field of xanthoma planum (Fig. 1). You see almost the entire picture made up of smaller and larger cell-like bodies filled with fine granules of fat and containing from one to several dozen nuclei, the groups of cells presenting a more or less lobular arrangement. Whether we regard these as connective-tissue cells, as endothelial cells, or as embryonal fat cells, the fact remains that nowhere else in the whole range of histology do we ever find endothelial or connective-tissue or fat cells developing into anything even remotely resembling the large, multinuclear, granulo-fatty cell which you see here. The so-called xanthoma cell, from this point of view, is absolutely unique. Furthermore, whatever refinements of staining we employ, we are unable to find in these cells anything of the usual protoplasmic structure of a cell body. The so-called xanthoma cells are, therefore, masses of granulo-fatty matter inclosed within a sharp wall and containing many well-preserved nuclei. This consideration has led Unna to deny the cellular nature of these bodies entirely, and to the distinguished Hamburg dermatologist belongs the credit of having distinctly separated on histological grounds the palpebral from the generalized form of xanthoma. He regards these "cells" as infarctions of intercellular lymph channels, with a peculiar fat into which naked endothelial nuclei have escaped. This view of Unna's has not, so far as I know, been accepted by any one. Moreover, the occurrence of such large aggregations of free endothelial nuclei would also be without a parallel in histology; nor can we understand why these fat masses lying free in the lymph channels should not be absorbed. It would appear, then, that all the various explanations of the evolution of these peculiar cells offered by histologists require the acceptance of facts that have no analogy in the entire range of pathology.

The explanation of the xanthoma cell which I shall offer you will involve nothing that is inconsistent with familiar pathological processes. The so-called xanthoma cell in xanthoma planum is a degenerated muscle fibre. In examining sections taken from the edge of a growing xanthoma I found a great part of the cutis filled with normal or but little changed striped muscle fibres. Most of these fibres run parallel to the orbicularis palpebrarum muscle; many, however, are oblique to the surface, while in places their direction is confused and irregular. On tracing back the course of the degeneration from the muscle fibre to the "xanthoma cell," the muscle first loses its transverse striation; then the primitive fibrillae fuse together. In this stage the fibres resemble coarse connective-tissue fibres, and no longer stain deeply with the aniline dyes, but the disposition of the nuclei in their midst reveals their true nature. Next, these glassy homogeneous fibres begin to disintegrate; here and there in the course of the fibre a patch of granular matter appears, while at the same time the muscle cells begin to proliferate. We find now such a homogeneous muscle fibre interrupted in its course by polynuclear masses of granulo-fatty matter that can not be differentiated from the xanthoma masses. Sometimes these granulo-fatty masses contain fragments of muscle substance still quite normal. These changes are beauti-
we find perhaps only a single almost normal muscle fibre in cross section in the midst of a mass of "xanthoma cells"; or, again, we find a well-preserved bundle of muscle fibres, three or four of whose fibres, however, are in various stages of degeneration, some of them resembling typical xanthoma cells (Figs. 5 and 6).

I shall not here enter into a minute account of this granulo-fatty degeneration of muscle substance, because a quite similar degeneration has been repeatedly described by far abler histologists than myself, and its details may be found in any text-book on pathology. Allow me to refer you to Waldeyer's celebrated paper on the degeneration of muscle fibres, many of whose pictures I can duplicate in my sections of xanthoma. I do not mean to imply that the xanthomatosus degeneration is identical with that found in typhoid fever or with that resulting from experimental myositis, but in many of their details the conditions are alike. There are, of course, many changes in the skin other than those I have just referred to, but they are secondary or merely incidental to the muscle degeneration, and have also been repeatedly described. I wish only to say that the small granular mononuclear "endothelioid cells" which many writers have regarded as the earliest stage in the evolution of the "xanthoma cell" are, in accordance with the facts that I have just described, probably only free muscle cells, such as occur regularly in degenerating muscle.

A word as to the occurrence of giant cells in xanthoma, to which Touton first called attention. Some writers designate the multinucleated granular xanthoma mass as a giant cell (e.g., Crocker, p. 493). It is perhaps needless to say that these bodies in no respect resemble giant cells, nor are they the giant cells that Touton described. In none of the hundreds of sections of xanthoma from the thirteen cases that I have examined have I seen a single true giant cell, nor do I know of any author but Touton who has seen them. It will be remembered, however, that Touton found giant cells in only one of his eight cases, and that happened to be from a nodule on the eye in a case of xanthoma multiplex. Now, while the nature of the pathological process in the common eyelid xanthoma entirely excludes the probability of giant cells occurring, it is not at all impossible that they may develop in the multiple form of xanthoma. I am indebted to Dr. Unna for a section of what he calls giant-cell xanthoma, which, as you know, he differentiates from the common xanthoma. Dr. Unna, it must be noted, did not see the case; the specimen was sent to him by a friend, with the clinical diagnosis of xanthoma. The specimen bears not the slightest resemblance to either the common eyelid xanthoma nor to the multiple xanthoma. In this connection permit me to remark that not everything is xanthoma that is yellow. So, for instance, Darier has recently shown that the xanthome élastique of Balzer and Chambard is a disease of the elastic tissue and not at all a xanthoma.

The thought will occur to you, as it did to me, "Is it possible, then, that muscle fibres have occupied the entire cutis as their degeneration products, the 'xanthoma cells,' do?" That this is indeed the case you can consider.

* An interesting observation of Chambard and Gouilloud's (Ann. de derm., 1883, p. 660) seems to afford a striking corroboration of the myogenetic origin of the xanthoma "cell." A small tumor, resembling a pendulous myolusus, was removed from the back of an adult. On section the tumor was found to be made up of muscle fibres and xanthoma cells. The case is presented as an example of the transformation of a congenital tumor: myome xanthomeateux développé dans un myolusus. I should not hesitate to pronounce it a pendulous myoma with xanthomatous degeneration of muscle fibres.

by this photograph (Fig. 7), which shows, in the midst of xanthoma tissue, a distinct muscle fibre directly beneath and parallel to the epidermis. Of course in many cases the muscle fibres do not fill the entire cutis, as in the sections before you, but occur in comparatively isolated bundles amid the normal tissues. Their degeneration then will yield such pictures as are shown in Crocker’s text-book or in Touton’s article; that is, comparatively isolated groups of xanthoma masses.

It remains to inquire into the origin of these muscle fibres. There can be only one answer to this question. They are clearly derived from the orbicularis palpebrarum, and are, no doubt, in their abnormal position the result of embryonal misplacement. It will be remembered that the fibres of this muscle are arranged in parallel bundles encircling the eyelids, and are normally separated from the epidermis by an extremely thin elastic layer of cutis, which, by the way, is free from any coarse connective-tissue bundles. At the inner canthus some of its fibres sweep around from one lid to the other, and from this region some fibres pass upward to the corrugator supercilii and others run downward and outward to merge with the general muscular layer of the face. From the inner canthus, too, Hornr’s muscle passes inward beneath the circular fibres of the orbicularis. No fascia or dense aponeurosis separates any of the face muscles from the cutis. It is clear that in this disposition of the muscles an opportunity for the embryonic displacement of fibres is readily afforded, and the chances of such a displacement’s occurring are greatest where the complexity of the arrangement of muscle fibres is greatest—namely, at the inner canthus.

Accepting the myogenic origin of xanthoma of the eyelids, regarding it not as a new growth but as a product of the degeneration of muscle, we find an explanation for a number of hitherto unexplained facts, clinical and pathological. (1) The absence of any clinical signs of tumor. (2) Its almost exclusive occurrence in the face, where peculiar muscular conditions prevail. (3) Its common arrangement in elongated plaques, whose long axis is parallel to the course of the orbicularis fibres. (4) Its heredity. (5) Its usual development after middle age, when degenerative processes are apt to occur. (6) The peculiar yellow pigment, which is always found in muscles undergoing fatty degeneration. (7) The structure of the tissue as I have described it above.*

The structure in the eight cases of generalized xanthoma that I have examined is so strikingly different from that of eyelid xanthoma that it seems remarkable that they should ever have been confused. I can account for this confusion only on the ground that some of the earlier cases of xanthoma of the eyelids examined were examples of xanthoma tuberosum that happened to be located on the eyelids. Such, I believe, was Waldeyer’s †

---

* Since this was written I have examined many more specimens of eyelids with a view to determining the normal distribution of muscle fibres in the cutis. I find, contrary to what is stated in the textbooks on the anatomy of the lid, that in a great many cases the muscle fibres are arranged in an extremely irregular manner. Small bundles are found so often separated from the main layer of muscle that it would seem as if what I have assumed to be an embryonal displacement of muscle fibres may be only a more extreme example of what is a quite common occurrence. This fact, however, does not militate against my argument. It is only the outlying fibres that undergoing xanthomatous degeneration, and the tendency to a particularly scattered arrangement of the fibres may well be inherited.

† Virchow’s Archiv, Band III.
showing a typical nodule of xanthoma multiplex from my case. You see a sharply circumscribed nodule surrounded by compact connective tissue located in about the middle of the cutis. Under a higher power only a single point of resemblance to the myogenetic xanthoma masses appears—namely, the cells of this new growth contain fat. But even this resemblance disappears on close inspection. The fat is arranged in distinct, though small, globules that are separated from each other by the meshes of a reticulated protoplasm. The nuclei of these cells are large, and the cells contain seldom more than one nucleus, only in the rarest instances as many as three, never the immense aggregation that we find in some of the myogenetic xanthoma masses. The details of the structure of my case of xanthoma tuberosum have been published by Unna in his Histopathology of the Skin, and I need not repeat them here. Being in possession of some alcohol specimens, the lack of which Unna deplored, I am able to some extent to supplement his description. The xanthoma neoplasm is a typical hyperplastic development of connective tissue in which connective-tissue cells develop into fibrous tissue on the one hand, or undergo fatty degeneration on the other, in varying proportions. At the periphery numerous fibroblasts may be seen, and the development of fibrous tissue preponderates; while toward the middle of the nodule the connective-tissue cells become more and more filled with fat until, yielding to fatty degeneration, they finally rupture, leaving the middle of the nodule a mass of fat and cellular detritus. Virchow * speaks of it as

into pure fat cells on the other. In seven of the eight cases of generalized xanthoma that I have examined this fatty degeneration occurred, and in the eighth (Robinson's case of elbow xanthoma) I failed to find it, either because I had but three slides from this case or because the nodule was of too recent formation to have undergone fatty degeneration. One point more strikes me as of interest. In the middle of the degenerated portion of the nodule a few connective-tissue cells, generally stellate, are always preserved, forming an island connected with the neighboring tissue by fine connective-tissue fibres which traverse the surrounding fatty detritus. This peculiar and absolutely characteristic patch of degeneration is very well shown in the photographs (Figs. 9, 10, and 11). Fig. 9 shows a degenerated portion of Fig. 8 under a higher power. Fig. 10 is from Dr. Morrow's case of xanthoma tuberosum. Fig. 11 is from Dr. Robinson's case of xanthoma diabeticorum.

Xanthoma diabeticorum differs histologically from xanthoma tuberosum in the following non-essential details only: (1) The new formation of connective-tissue cells is not sharply limited to one or more nodules, but is a more diffuse process. (2) The entire process is located more superficially in the cutis. (3) The tendency to fatty degeneration is more marked, and the formation of fibrous tissue less apparent. It results, therefore, that in a single section there will be numerous foci of degeneration. Dr. Robinson was, I believe, the first to describe these in xanthoma diabeticorum under the name of retrograde changes. Török,* who lacked an opportunity to examine personally this form of xanthoma, dwelling on Dr. Robinson's description of degenerative changes in xanthoma diabeticorum, insists on

---

* Virchow's Archiv, Band iii.

* Ann. de derm. 1893.
placing the two forms of generalized xanthoma in different classes, because in the one, according to previous descriptions, there is degeneration, and in the other there is not. My eight cases, however, make it clear that he is mistaken.

A few words on the general pathology of xanthoma multiplex. The earliest writers on the subject were struck by the association of affections of the liver and xanthoma. As the cases have multiplied, the correctness of this observation has been verified. The statistics on this point are somewhat unreliable, because in many cases no distinction has been made between xanthoma planum and multiplex. According to Crocker, in four fifths of all the recorded cases of xanthoma multiplex above puberty, about sixty in number, there was chronic jaundice, due to severe lesions of the liver.

At one end of this series of lesions we should have the persistent fibrous node of rheumatism; at the other, the nodule of diabetic xanthoma, with its marked tendency to fatty degeneration; while between them, intermediate in its formation of fibrous tissue and its tendency to undergo fatty degeneration, would stand the nodule of common xanthoma tuberosum.

Permit me, in closing, to sum up briefly the conclusions arrived at in this paper: (1) Xanthoma palpebrarum vulgare is not a neoplasm; it is the product of the degeneration of embryonically misplaced muscle fibres. (2) It bears no histological relationship whatever to xanthoma tuberosum disseminatum. (3) The common xanthoma tuberosum and xanthoma diabeticum are similar processes. (4) They are both connective-tissue neoplasms in which the relative proportion of fibrous tissue and connective-tissue cells varies in different cases. In both the cells undergo a fatty degeneration, resulting in the destruction of the cells and ultimately in the more or less complete disappearance of the nodule. The process is more diffuse and the degeneration more rapid in the diabetic form. (5) Generalized xanthoma is an irritative process whose cause must be sought in some systemic disturbance.

**Explanation of Figures.**

Figs. 1, 7, 8, 9, 10, and 11 are photomicrographs, and are sufficiently described in the text. Figs. 2, 3, and 4 were drawn by Dr. Ira Van Giesen, who wrote the description which follows. The sections are from formalin specimens, and are stained with polychrome methylene blue; Leitz immersion, 1/5; lowest ocular.

"Fig. 2. Three striped muscle fibres from the lower middle cutis. Fibre c is normal except at the left-hand extremity. The right-hand three quarters of the fibre show transverse and vertical striation and Krause’s lines distinctly. At the point N the striation becomes indistinct and disappears. The fibre here has a homogeneous appearance and a change in its calibre; it becomes narrower, and again over the distance c’c” is enlarged into a homogeneous darkly staining mass of degenerated hyalinlike muscle substance.

"The fibre a shows a further stage of this conversion into clumps and segments of darkly staining homogeneous degenerated muscle substance. Between these larger and smaller segments, K—K’, the sarcolemma S S S is apparently empty and collapsed. At the left extremity of the fibre two sarcolemma nuclei are seen within the narrowed sheath.

"In the fibre b are two of these homogeneous hyalinlike degenerated segments of muscle substance, and the rest of the sarcolemma sheath is filled up with a fine network, in the nodal points of which are slight thickenings. The sarcolemma nuclei have proliferated to a considerable degree.

"Fig. 3. Three degenerated muscle fibres from the same region. Fibre A shows same appearances as fibre a in Fig. 2. At K’ a globular mass of degenerated muscle substance appears to have a hollow centre. In fibre C a similar phase of degeneration is shown, but apparently more advanced, as the degenerated segments show a tendency to become hollow and vesicular, as at L and L’, and at G to become finely granular. The
fibre $B$ shows a transition stage from this phase of degeneration to the production of structures indistinguishable from xanthoma cells, $X$, at the left-hand extremity.

"Fig. 4. Portion of three muscle fibres from the lower cutis. The lower fibres show vertical striation distinctly. The upper fibre stops abruptly and its thickened sarcolemma sheath passes on, emptied of muscle substance and containing a number of proliferated sarcolemma nuclei."

Figs. 5 and 6 were drawn by Mr. Veenfliet, artist to the pathological laboratory of the New York State hospitals.

Fig. 5. Alcohol specimen; stain, haematoxylin and picro-acid-fuchsin; Leitz objective, $\frac{1}{2}$; ocular 2. Cross section of an isolated muscle fasciculus from the middle cutis. Most of the fibres show a peculiar fragmentation. At $MX$ several of the fibres present a network like that of fibre $b$ in Fig. 2, which can not be distinguished from $X$, a xanthoma mass.

Fig. 6. From the upper middle cutis; Fleming specimen; safranin; objective D; ocular 2. Shows a number of muscle fibres in various stages of degeneration in longitudinal section. The fibre $M$ presents a glassy homogeneous appearance. $MP$ is a fibre whose nuclei have greatly proliferated, while at its end, $MX$, it is converted into a fine granular xanthoma mass. $MT$ shows the same fatty granular appearance, stained black by the osmic acid, throughout its length, with occasional nuclei in the mass. $MTX$ appears to be a similar fibre, showing signs of separation into smaller masses resembling xanthoma cells. Typical xanthoma "cells" are shown at $X$.

64 East Fifty-eighth Street.

THE RELATION OF OPHTHALMOLOGY TO GENERAL MEDICINE.

By G. Griffin Lewis, M.D., Syracuse, N. Y.

I wish to present for your consideration a paper, the subject of which, at least, ought to be of some interest to the practitioner of general medicine, inasmuch as he is frequently called upon to treat many affections of the eye or in which the eye participates, and therefore should be more or less interested in the part played by that organ in the causation of functional nervous disturbances and reflex conditions. Scientific researches have vindicated the position claimed for ophthalmological practice as covering a multitude of physical ills, and in considering my subject I shall endeavor, as far as possible, to confine my remarks to matters of ordinary occurrence in general practice.

In the eye and its accessories is found a small specimen of every tissue met with in other parts of the body, as well as tissues peculiar to itself.

It is easy, therefore, to understand how many diseases may affect these different tissues, and how each one affords points of diagnostic importance.

With scrofula we may have phlyctenule of the conjunctiva or cornea, styes, conjunctivitis, eczema of the lids, or blepharitis. With rheumatism or gout we may have iritis, chorioiditis, or paralysis of the external ocular muscles; with malaria, retinal haemorrhages, spasm of accommodation, or lesions of the vitreous. Syphilis is credited with being the cause of fully three fourths of all cases of chorioiditis and atrophy of the optic nerve, one half of all cases of iritis, and one third of all ocular palsies.

The acute febrile and infectious diseases, which lower the resisting power of the tissues and render secondary infection more easy, are particularly liable to be accompanied by some ocular lesion; thus measles may show ocular lesions during any of its stages.

Catarhal conjunctivitis, phlyctenula, dacyrocystitis, and retinitis are frequent complications of scarlet fever, chicken-pox, and small-pox. During the epidemic of small-pox in Vienna in 1889 and 1890 nine per cent. of the cases presented some ocular lesion.

With diphtheria we may have retinitis and paralysis of the ciliary or external ocular muscles; with influenza, conjunctivitis, keratitis, corneal ulcers, iritis, cyclitis, chorioiditis, or affections of the internal or external ocular muscles. Anæsthesia or inflammation of the cornea, retinal haemorrhages, or chorioiditis may occur in typhoid fever. Puerperal fever, intermittent fever, and pneumonia are frequently accompanied by retinitis.

Diseases of the circulatory system, such as anæmia, chlorosis, hydreaemia, pyæmia, and atheroma, are liable to give rise to some such ocular lesions as conjunctival and retinal haemorrhages, chorioiditis, paralysis of accommodation, and œdema of the lids. Diseases of the kidney are especially liable to be accompanied by eye complications, and often lesions of the fundus may be discovered by the ophthalmoscope before any other symptoms are manifest. Frequent ophthalmoscopic examinations of the eye should therefore be made in all cases of pregnancy in which the existence of a neurorretinitis not only justifies but demands the induction of premature labor. With diabetes we may get catarracts, keratitis, corneal ulcers, hemorrhages of the conjunctiva, optic neuritis, atrophy of the optic nerve, and paralysis of the external ocular muscles, and with uremia or Bright's disease we get retinitis, retinal haemorrhages, optic neuritis, palsies, and iritis.

Statistics show that nearly all cases of albuminuric retinitis prove fatal within two years after the ocular lesion manifests itself.

I have recently had under my care a patient with a bad iritis, which continued to grow worse in spite of all treatment until an examination of the urine revealed about thirty per cent. of albumen, and he was sent to his family physician for the proper constitutional treatment, whereupon the percentage of albumen rapidly diminished and his eye recovered. This one case illustrates the necessity of an early examination of the urine in a large percentage of our eye cases.
Edema of the lids is one of the most common symptoms of trichinosis and arsenical poisoning. It may also occur in lesions of the heart, lungs, or kidneys. Edema of the conjunctiva is an early symptom in cerebro-spinal meningitis. Blepharospasm may occur during mental excitement, chorea, hysteria, or epileptic seizures.

Ptosis is frequently an indication of some brain lesion, especially in the frontal lobe of the cerebrum just in front of the fissure of Rolando. Styes usually indicate an anaemic or strumous condition, or some derangement of the digestive or reproductive organs. Painful ulcers of the cornea are due to a lesion of the fifth nerve. Spontaneous, recurrent conjunctival hemorrhages in old people are of a serious significance, and often indicate possible hemorrhages into the brain and the existence of kidney disease. Nystagmus may be the result of brain lesions, especially in the pons, or it may be a premonitory symptom of disseminated sclerosis. Hemianopsia may occur suddenly as a sole manifestation of cerebral hemorrhage, or is often a premonitory symptom of paralysis with a lesion or tumor of the brain.

Paralysis of the external ocular muscles may be the result of syphilis, tabes, diphtheria, diabetes, progressive muscular atrophy, or basilar affections of the brain. An eye paralysis, however simple it may seem, is always a just cause for suspicion of trouble to come, and demands prompt and thorough examination of the patient.

Abscesses of the lower lid are sometimes the result of abscesses of the gums. Affections of the laerymal apparatus may be due to an acute or chronic coryza. A large proportion of the cases of phlyctenula of the conjunctiva and cornea are due to eczema of the nose, and usually show a depraved condition of the system and improper diet. Herpes of the cornea is not of uncommon occurrence during bronchitis or pneumonia. Spontaneous retinal hemorrhages are often the forerunners of cerebral hemorrhages.

Indigestion frequently causes feeble accommodation and weakness of the external ocular muscles.

The eyes are projecting in hydrophobia, hydrocephalus, asphyxia, and exophthalmic goitre; they are sunken in collapse and cholera; they are rolling in epilepsy and meningitis; they are staring in apoplexy, convulsions, meningitis, and febrile conditions; they are dull and expressionless in dementia and typhoid conditions. The pupils are dilated in delirium tremens, apoplexy, anemia, insanity, tabes, uremia, hysteria, collapse, syncope, coma, drowning, epilepsy, and nearly all cerebral affections with increased intracranial pressure. They are contracted in sunstroke, typhoid fever, and hemorrhage of the pons.

They are unequal in general paralysis, tabes, compression of the brain, and posterior spinal sclerosis. If dilatation of the pupil follows contraction during an attack of apoplexy the prognosis is very grave. Sudden dilatation of the pupils during complete anaesthesia is an indication of an impending asphyxia.

Monocular dilatation of the pupil and paralysis of accommodation are suspicious premonitory signs of insanity.

As so many general affections are accompanied by internal lesions of the eye an ophthalmoscopic examination is of great assistance in making a diagnosis, especially in cerebral and spinal affections. The retinal vessels derive their supply from the same source as the greater part of the brain, therefore derangement of the cerebral circulation is often accompanied with simultaneous changes in the retinal vessels. Especially is this true in chronic conditions; thus, an examination of the color sense and visual field is often of extreme value in the localization of intracranial affections. The eye and its appendages being supplied by six of the twelve cranial nerves, it is no wonder that intracranial lesions seldom exist without some ocular symptoms. If the lesion is sudden, it is probably of vascular origin; if acute, developing within a few weeks, it is probably of inflammatory origin, and if chronic and of slow development, it is probably due to a neoplasm causing a gradual increase in the intracranial pressure.

Optic neuritis is a characteristic finding in a large number of brain lesions with increased intracranial pressure, such as abscess, tumor, hemorrhage, and meningitis, especially if they are located in the cerebellum or adjacent parts, in which case it is usually due to direct implication of the optic nerve. It is usually bilateral. If unilateral or more pronounced on one side, it is generally found on the same side as the lesion, which is then, as a rule, located in the anterior part of the brain. The neuritis may be accompanied by contraction of the visual field and color disturbances, and if the lesion is near the base of the brain there is usually some edema of the lids, exophthalmos, pain, and photophobia.

When there is increased intracranial pressure the pupils are nearly always dilated and react poorly to light, excepting when the lesion extends within the ventricles, in which case they are very much contracted.

Other ocular symptoms which may occur in lesions of the brain are hemianopsia—as a rule binocular, or when monocular it is usually on the side opposite the lesion and due to irritation of the opposite hemisphere; exophthalmos and edema of the conjunctiva due to pressure upon the cavernous sinus and ophthalmic vein; convergent strabismus due to pressure on the sixth nerve, which is especially exposed to pressure on account of its long course in the skull; atrophy of the optic nerve, due, in all probability, to injury of the optic tracts, and choked disc caused by the entrance of fluid into the sheath of the optic nerve. The latter is the most frequent and most important symptom in the diagnosis of brain tumor of whatever kind or wherever situated, being present in fully two thirds of the cases. It might be well here to correct the erroneous impression which
many have that choked disc and optic neuritis are one and the same thing. The former is a simple edema of the nerve, without inflammatory symptoms, and may not interfere in the least with the vision; while the latter is an inflammation of the nerve and always interferes with the vision proportionately to the amount of inflammatory action.

All irritative eye symptoms, such as spasm, photophobia, lacrimation, etc., usually decrease or subside with the improvement or disappearance of the intracranial affection, but symptoms due to a destruction of tissue will persist.

Too much stress can not be laid upon an early diagnosis of certain affections of the eye, such, for instance, as iritis, glaucoma, optic neuritis, sympathetic ophthalmia, gonorrheal conjunctivitis, corneal ulcers, and retinal hemorrhage. Mistakes in diagnosis are especially liable to be made in cases of iritis and the wrong treatment pursued, until adhesions are formed between the iris and lens capsule, making the eye practically blind for life. Special caution should be taken in discriminating it from glaucoma, as the treatment of the two diseases is entirely different. This mistake in diagnosis, followed by the use of atropine, has destroyed many an eye and caused many a suit for malpractice. In iritis the pupil is small, the cornea transparent and sensitive, and the tension normal; while in glaucoma the pupil is somewhat dilated, the cornea steamy and insensitive, the tension increased, and the anterior chamber shallow.

In no branch of our work is greater evil to be expected from a wrong or neglected diagnosis and treatment than the one comprising the sympathetic diseases of the eye. Wounds in the ciliary region of one eye may at any time, from a month to forty years, be a source of sympathetic trouble in the other eye. This is especially liable to occur when the tension of the injured eye is less than normal. The early symptoms of sympathetic ophthalmia are photophobia, lacrimation, impairment of vision, ciliary neuralgia, contraction of the visual field, and impairment of accommodation.

Certain drugs administered internally are capable of causing ocular symptoms: thus, edema of the lids may be caused by arsenic, chloral, hydrocyanic acid, and quinine; twitching of the lids by eserine, pilocarpine, and strychnine; ptosis by lead; conjunctivitis by arsenic, belladonna, bromide of potassium, chloral, eserine, iodine, iodide of potassium, muratic acid, nitric acid, podophyllin, and resorcin; anæsthesia of the cornea by apomorphine, sulphonal, and quinine; paralysis of the external ocular muscles by alcohol, cocaine, lead, and quinine; dilatation of the pupil by anconine, ataline, belladonna, caffeine, cocaine, conium, cyanide of potassium, cannabis indica, cantharides, digitalis, ergot, gelatin, henbane, hydrocyanic acid, hyoscynamine, prussic acid, quinine, and stramonium; contraction of the pupil by carbolic acid, chloral, eserine, iodoform, morphine, nux vomica, opium, oil of bitter almond, pilocarpine, and salicylate of sodium; slughisness of the pupil by alcohol, carbolic acid, gelatin, and hydrocyanic acid; paralysis of accommodation by belladonna and lead; spasm of accommodation by eserine and tobacco; floating bodies in the vitreous by ergot, naphthaline, and tea; retinal haemorrhage by carbolic acid, lead, mercury, and phosphorus. Inflammation of the optic nerve may be caused by arsenic, cannabis indica, lead, phosphorus, and tobacco; atrophy of the optic nerve by cannabis indica, felix mas, lead, mercury, quinine, salicylate of sodium, and tobacco. Glaucoma may be caused by belladonna and cocaine; exophthalmes by carbolic acid, hydrocyanic acid, and quinine; lacrimation by antipyryme and iodide of potassium; photophobia by cannabis indica and tobacco. The color sense may be disturbed in various ways by drugs; for instance, Daltonism may be caused by ergot, lead, quinine, and tobacco; yellow vision by amy! nitrite, chronic acid, digitals, picric acid, and santonine; violet vision by cannabis indica, and red or blue vision by iodeform.

We have very rudely and hurriedly considered some of the affections and toxic conditions in which the eye participates, and now I wish to call your attention to the importance of recognizing the existence of serious errors of refraction and muscular insufficiencies.

There is hardly a subject in medicine that has received more attention of late than the effect of eye strain upon the nervous system, and especially its connection with headache. It is the chief complaint of a great majority of my patients, and its relief by ophthalmic treatment has been most satisfactory. When I first began special work it seemed to me that a great many ophthalmologists had been inclined to give undue prominence to ocular defects as a cause of headaches; but after an analysis of over five thousand refraction cases, as they appear on my case books since 1891, I find that of the entire number over eighty per cent. suffered more or less with headache.

The location and character of the pain usually depend on the kind and amount of ocular defect. I have found, as a rule, that headaches from refractive errors are usually frontal or orbital, while those due to muscular insufficiencies are more often occipital or cervical. Many patients with ocular defects complain little or not at all of ocular symptoms. One may have a large degree of ametropia, and yet declare that his eyes are perfect. He has no pain, no soreness, no hyperemia of the conjunctiva, no local symptoms whatever. Thus the effects of eye strain may be divided into two classes—viz., those limited to the eye itself and those presenting systemic or extra-ocular results.

The function of the eye is to form a perfect image of an object upon the retina in precisely the same way as a photographer's camera does upon the sensitive plate. When the antero-posterior diameter of the eyeball is too short, or the media too weak in refractive power, as in far-sighted people, the rays of light strike
the retina before they are brought to a focus, and the muscle of accommodation is put to an excess of effort to bring the focus forward so that it shall be upon the retina. When the cornea is unequally curved in different meridians, as in astigmatism, giving the eye two foci instead of one focus, the retinal image is blurred and the muscle of accommodation seeks to neutralize this corneal asymmetry by an unequal contraction. When there is an insufficiency or lack of muscular balance in the external ocular muscles, the weaker muscles are put to an excess of effort in order to maintain binocular vision. Thus we may clearly see that the great effort on the part of the ciliary and external ocular muscles to maintain accurate binocular vision spurs the oversensitive nerve centres to extraordinary exertion. An astonishingly large proportion of the population of all civilized countries have weak eyes. I say civilized countries, for it is a recognized fact that eye strain is, in a large degree, the result of civilization.

Astigmatism and far sight may be just as prevalent among the savages, but their accommodative apparatus is not being constantly strained by reading, writing, sewing, and many of the other accomplishments of civilization. This is the reason why so few nervous disorders exist among uncivilized nations.

That eye strain is one of the most important of all factors that tend to produce functional nervous disease has been demonstrated by the recorded observations and experiences of a multitude of skilled and trustworthy physicians. Among the nervous affections whose atiology may frequently be traced to eye strain are headache, vertigo, hysteria, neuralgia, neurasthenia, chorea, epilepsy, and nervous prostration. Digestion and assimilation may be directly and profoundly disordered by eye strain. Cases of nausea and vomiting, connected with the use of the eyes and relieved by wearing the proper glasses, are quite numerous. I believe that night terrors, insomnia, non-restful sleep, and nocturnal incontinence of urine in children, working hard at school, are the direct result of eye strain. Too much stress can not be laid upon eye strain as a factor in the production and aggravation of neurasthenia, among the most important signs of which are eye symptoms such as contraction of the visual field, paralysis of accommodation, hyperaemia of the conjunctiva, and a convergent or divergent strabismus. A very frequent and interesting symptom is an inability on the part of the patient to entirely close his lids when standing with his legs together.

That there is a direct relationship between anomalies of the eye and epilepsy no one can deny, but how much it amounts to, or how often it is encountered, is still a question. About twenty per cent. of all epileptics have some congenital anomaly of the eye, especially some form of refractive error. Some time ago at a meeting of the Ophthalmological Society of the United Kingdom, a report on the refractive condition of epileptics was made by Dr. Dodd, based upon the examination of a hundred epileptic subjects, and the conclusions drawn by Dr. Dodd were, first that “errors of refraction may excite epileptic seizures; second, that the correction of the refractive error is of value in the treatment of epilepsy; third, that other sources of irritation may be suspected when a correction of the refraction fails to afford relief.”

In my opinion a very good rule to follow in getting at the etiology of epilepsy would be to instill atropine into the eyes of every case under thirty years of age, and if, after a complete paralysis of accommodation, the convulsions still continue, we may be certain that it is not due to a refractive error.

From the foregoing facts it is evident that an abnormal condition of the eye may be a fruitful source of reflex disturbances, and that we have it in our power to render the aid to Nature that will relieve a great deal of suffering, not to mention the improvement in vision to be gained by many in the proper adjustment of glasses to their eyes.

SOME ASPECTS OF CHRONIC MALARIAL INFECTION AND THEIR TREATMENT.*

By W. H. THOMSON, M. D., LL. D., PHYSICIAN TO ROOSEVELT HOSPITAL.

The trend of our present discussion on the subject of malaria illustrates at least one aspect of the great change within our own time in the whole conception of the nature of infectious diseases. In September, 1862, after two years’ experience as hospital physician at the New York Quarantine, I published a paper in which it was argued that the chief clinical facts about the communicable diseases would be explained only on the assumption that they were due to micro-organisms. This statement was then met with general ridicule, the prevailing view being that these diseases were caused by volatile poisons emanating from the bodies of the sick or pervading the atmosphere. In 1855 the Massachusetts Medical Society addressed a statement to the public that Asiatic cholera was not at all contagious, but was instead a miasmatic disease diffused through the air. Even long after pyaemia following upon surgical operations was shown to be due to bacterial infection of wounds, surgeons operated in a cloud of antiseptic spray to prevent the germ-laden atmosphere from infecting the cut surface. Gradually this modified conception of floating micro-organisms gave place to the conviction that pathogenic germs do not float about in the air so much as they cling to surfaces and to things. But malaria, on the other hand, still held its own, as its name implies, as an undoubted evil air, a true miasm which rises from the earth’s surface, particularly at

* Read at the general meeting for the discussion on malaria at the New York Academy of Medicine, April 20, 1899.
night, and is thus inhaled with our breath. The demonstration, however, that it too is caused by a micro-organism suffices to remove it equally from the list of miasmatic diseases, for there can be no such thing as a living vapor or gas. Whether after this we can believe in the existence of miasmatic diseases at all, or, in other words, in true malaria, is a question.

On this great subject, therefore, our point of view is wholly changed. What remains for us now to study is the birth and life history of an organism, and this turn in the problem from the pursuit of an ill wind to the pursuit of a definite living thing undoubtedly marks one of the greatest gains in the history of medicine, an advance which was not possible so long as attention was turned in quite a wrong direction. Whether also the line of investigation is to be still further defined, and the mode of entrance of the infection to be sought neither by the lungs nor by the alimentary canal, but by direct inoculation with insect bites, is not yet settled; but a positive demonstration that the infection can be thus caused raises a strong presumption that this is the ordinary course, because inoculation is a method so peculiar and specific that it is doubtful if there are other wholly different methods equally operative. Should the inoculation theory be finally established, the ultimate control of this worldwide scourge would certainly be in sight, and Medical Science could then say that there should be no more unhealthy climates, but only unhealthy places, which, moreover, she could thoroughly disinfect if properly supplied with the means.

Functional nervous affections due to the toxine of malaria are very common, but at present I would refer only to its production of periodical neuralgias. I do not know that I have ever met with pains of greater severity than in some of those patients whom I have seen in consultation with their physicians. Their commonest form is a violent headache, generally diurnal and recurring at the same hour of the day or night; but I have also met with typical attacks of the kind in the spine, in the sides of the chest, in the abdomen, and in the pelvis. The history of a malarial infection, however, is not always certain, for in two cases the antecedent was an attack of epidemic influenza. In the Medical Record, March 17, 1894, I published the histories of four cases of this kind, and since that I have met with a number of others. The attacks of pain last about as long as ordinary paroxysms of febrile malaria, followed by remission or total intermission until their times of recurrence come round. I mention these cases more particularly on account of the action of a drug which I have found specific in controlling the pain, and in finally ridding the patient of it, and that is ergot. In every case in which I had recommended it, quinine in heroic doses, as well as Warburg’s tincture, antipyrine, and other remedies, had wholly failed to relieve the paroxysms, while ergot, given in drachm doses of the fluid extract, either by the stomach or per rectum, and repeated in two hours if the first dose failed to fully relieve the pain, was uniformly successful. It was curious that in several of these patients doses of only twelve grains of quinine caused symptoms of cinchonism if administered along with the ergot, which did not occur with far larger doses of quinine administered previously.

Every remedy which exerts a marked influence on a given disease is on that very account liable to misuse by mere routine administration, and thus may frequently seem to fail. It is instead a good principle in therapeutics that the better the remedy the greater should be the care in its administration. Quinine in the treatment of malarial disease is certainly no exception to this statement. Thus it is often prescribed as if it were such a specific antidote that, if a recurrence of the chills is prevented by it for a week or so, its administration is then suspended. I would advocate, on the contrary, the doctrine that the occurrence of a single true malarial attack implies an infection whose systematic treatment should not cease for at least six weeks, if not much longer. Were this rule adopted after every first attack, when the recuperative powers are not seriously lessened, I believe that there would be but few relapses or chronic infections. Subsequent attacks to such a course would then be due to reinfections from without and not to relapses, and it is well to bear this distinction in mind. A relapse distinctly shows that the infecting organism had not been got rid of, and that enough remained instead to multiply again. That this often occurs in malaria is shown by its persistent recurrence in patients, notwithstanding their removal to non-malarious localities, where reinfection could not happen. Now that we definitely know what our enemy is, further researches are greatly to be desired as to the length of time the parasites remain living in the blood, and what their life history in an individual may be. As Professor Theobald Smith showed at our last meeting, the blood parasite of the Texas cattle fever has been found to exist actively in the blood for as long as five years. In human malarial disease on the other hand, numerous observations on the incubation period following the first infection show that it varies greatly in different individuals. Thus, some years ago a party of seventeen persons from the town of Bex, in Switzerland, where malaria is unknown, made a trip to an Italian town for sea bathing, and the entire company subsequently developed ague after returning home, the majority within three weeks, but others not till the second, third, and fourth months after the date of their infection.

It is this feature of latency which often renders this affection so intractable by inducing patients to drift on from month to month unsecured because they take no systematic course, but only short medication after some febrile relapse, until their powers of resistance are much lowered or permanent organic injury has re-
sulted. But a watchful observation of such patients during the latent stages often would show instead that they were actually diseased, by such facts as periodic marked increase of the excretion of urea and of phosphoric acid at definite times in the twenty-four hours, as shown by Ringer; also, without their being aware of it, a temporary febrile state accompanied by a sense of muscular fatigue. Likewise, the digestive functions are constantly getting out of order, but in a fashion quite characteristic of malarial infection, as are also many of the accompanying nervous derangements. Let some unusual systemic strain now happen from exposure or exertion, and the familiar old chills and fever return, with rapid enlargement of the liver and spleen. Quinine is now taken again, but with evidently less effect than before, until at last it seems to make the patient worse rather than better. We are all familiar with such clinical histories and term them obstinate cases, whereas they are usually cases of neglect of continued treatment of the original infection, rather than of a reinfection, ending sometimes in a fatal anæmia. Indeed, I have often questioned whether some cases of progressive anæmia do not bear the same relation to a long antecedent malarial infection that some textural nervous diseases bear to a long antecedent infection by syphilis. However that may be, latent malarial infection should not be allowed to carry on its hidden mischief. Now that examination of the blood affords us as certain evidence of the presence of malarial disease as examination of the urine detects kidney disease, patients should be recommended to have their blood tested at intervals for this parasite for at least nine months after apparent recovery.

The curability of a malarial infection varies so much, according to the person infected, that in no other disease is the futility so often exemplified of mere dosing with drugs irrespective of the individual's constitution. A large number of persons, as a regiment of soldiers, for example, are infected under identical conditions as to time and to locality. The majority of them never reach the stage of illness from it, while the rest are invalidated in the most varying degrees, from a few days to a whole year. Hence, spontaneous cure, without any treatment, must be predicted as not uncommon, and due to individual powers of resistance. Chronic malarial infection, therefore, implies a personal susceptibility, original or acquired, which calls for particular management. During the months of September and October last I had a hundred soldiers with Cuban malarial poisoning admitted to my wards at the Roosevelt Hospital, and I found that quinine had been given to every one of them in doses varying from fifteen to ninety grains daily for periods varying from four weeks to three months, but without true remedial effect, the blood in every instance showing the plasmodium apparently indifferent to the presence of this drug, though many of the patients were quite cinchonized by it. This clinical fact, however, by no means shows that quinine is not the medicine for malarial disease, for, on the contrary, it is the first remedy to be given for this disease. With quinine employed in the right way, and with proper adjuvants, every case of malarial disease ought to be cured, however chronic or obstinate. Owing to the practical interest of the subject I would take the liberty in closing to give a brief sketch of the course of treatment which I should recommend. First, begin with a mercurial laxative, given toward the close of the febrile paroxysm and made to act within six hours. Mercurial purges are the best agents against the intestinal self-infection which occurs in every fever, though notably in scarlatina and in typhoid fever, but just as certainly in ague as well. Moreover, a special reason for their use in this fever is that quinine is an unstable alkaloid, readily decomposed by too long a sojourn in the alimentary canal before absorption. Strychnine heated to 140° F., though its chemical constitution seems unaltered by this degree of heat, yet is rendered wholly inert; and that the portal congestion characteristic of malarial fever much delays both the absorption and the action of quinine is shown by the fact that quinine given hypodermically produces cinchonism in a healthy person in one third the dose which is needed to produce that effect when given by the mouth; while in conditions of hepatic congestion, however produced, the difference is still more marked.

Having thus promoted the absorption of the drug by the preliminary purging, the time for the administration of the quinine is the next important indication. Among the hundred soldiers mentioned, while the rest had been relieved by the treatment to be referred to presently, there remained two who continued to show a daily febrile rise for some fourteen days. As often occurs with infection by the estivo-autumnal parasite, it was difficult to determine the exact time of the onset of the paroxysms in these two cases, but a careful inspection of the temperature chart finally led to altering the time for the administration of the quinine, the dose remaining the same as before, whereupon the fever was speedily broken after the time change. My own observation on this point coincides with that of many others, that the entrance of the fullest doses of quinine into the circulation should coincide as nearly as possible with the time of sporulation in the life cycle of the parasite—that is, from one to two hours before the time for the chill—because the more adult forms seem to be less susceptible to the drug. Were it not that large single doses of quinine are prone to irritate the stomach and thus delay absorption, particularly when gastritis due to hepatic congestion is already present, the appropriate dose might be given at once. But for the reason stated I prefer to prescribe its administration in three equal doses, an hour apart, the last from one to two hours before the expected paroxysm.

It has been a matter of common experience, especially in the treatment of malarial fevers in the tropics, that the action of quinine appears to be promoted by the simultaneous administration of various spices. The remarkable furago of compounds in Warburg's tincture, the original formula of which is said to have called for seventy-six ingredients, doubtless owes much of its efficacy in chronic malarial disorders to its predominant proportion of spices. I have been accustomed, therefore, for many years to prescribe powdered ginger along with quinine, in equal quantities, and I have felt convinced that I could get along with smaller doses of the quinine itself by adding the ginger in the treatment of our ordinary intermittents. I have known ginger alone, administered in a large dose in hot milk, to break up chronic ague of the quartan type when quinine had conspicuously failed. In a number of cases I have also added pulverized capsicum, a grain to four of quinine, but it is curious that the first dose of this combination often acts as a free purgative.

But cases of chronic and severe malarial infection are continually occurring in which quinine seems wholly to fail to cure the disease. Such a problem confronted me when my colleague at the Roosevelt Hospital, to whose service I succeeded on the 1st of September, told me that the soldiers in the wards had been there from the 17th of August, and that, though he had tried every form of administering quinine as to dose or method, as well as Warburg's tincture, and free administration of arsenic, yet the general results had been very unsatisfactory. In some cases large doses of quinine held the temperature for a few days, but only to be followed by relapses. The best results with this drug were in patients who had true intermissions, but these were a small minority, the fever with most of the others running a continuous but very irregular course, the predominant form of the plasmodium being of the astivo-autumnal variety. I determined then to try the most ancient of known remedies against malarial poisoning—namely, opium—as an adjuvant to quinine. Forty-seven of the actively febrile cases, with temperature ranging from 103° to 106° F., were chosen, while check cases, in equal number at first, were left with the former treatment. I chose the camphorated tincture of opium as the most suitable preparation on account of its stimulant properties, and gave it in three daily doses of half an ounce each, with doses of fifteen grains each of quinine and of ginger twice a day.

As I have already published a detailed account of our observations on the effects of the camphorated tincture of opium as an adjuvant to quinine in these Roosevelt Hospital cases, I will only quote from it the following: In twenty-two, or forty-seven per cent, of the number who took paregoric, the result was an immediate break in the fever—that is, the temperature fell to normal in twenty-four hours, nor did it rise again afterward. This effect was the more impressive because in every instance they had been unavailing treated with quinine and Warburg's tincture for an average period of ten days previously without reducing the fever. Of the remaining twenty-five out of the forty-seven there were ten patients, or about twenty-one per cent., in whom it took from thirty-six to forty-eight hours to reduce the temperature to normal. No relapse was recorded in the case of any patient who took the paregoric treatment after the temperature was once reduced to normal.

Sir William Roberts, chairman of the British royal commission appointed to investigate the opium question in India in the years 1893-94, maintains that the antimalarial properties of opium are due to its alkaloid, commonly named narcotine, but which he maintains should be termed anarcoine, as it has neither anodyne nor narcotic properties. The proportions of the two alkaloids in Smyrna opium are morphine, eight per cent.; narcotine, two per cent.; while in Bengal or India opium the proportion is morphine, four per cent., and narcotine, six per cent. In many cases, according to the voluminous statistics of British India surgeons, narcotine administered alone has been more efficacious than quinine as an antiperiodic. One of the most striking effects of the paregoric treatment in my hands was its unlooked-for antistuporous properties, so to speak. Instead of manifesting the usual symptoms of opiates, many of the actively febrile patients were roused by it out of the characteristic lethargy of the fever, and even in the weak pyretic patients with pronounced anaemia the testimony was almost uniform that they felt better and stronger after taking it, the effects appearing the very reverse of narcotic and more like those of a cardinc and general nervous stimulant. I have noted analogous results also in private practice in the treatment of chronic malarial infection, notably when the patients complained of repeated headaches and general malaise, so that I have no hesitation in recommending this preparation of opium as one of our most trustworthy agents in the management of this common cause of prolonged invalidism in our climate.

PHTHISIS:
ITS ETIOLOGY AND TREATMENT.

By GEORGE D. BARNEY, M.D.,
BROOKLYN.

The importance of my subject is without bounds when we pause to consider the fearful fact that about one sixth of the human race suffers from its ravages today. However, few medical men of experience will say that phthisis is an incurable disease, at the same time admitting that all cases are not curable; indeed, the percentage of curable cases is quite small, and yet large enough to encourage active and intelligent treatment.

To effect a cure in phthisis the conditions of cure must exist—i. e.:
1st. The absence of hereditary predisposition.
2d. The early recognition of the disease.
3d. The resisting power of the organism.
4th. The organic state of the patient.
5th. The early occurrence of hemoptysis.
6th. A natural tendency to a fibrous rather than a caseous metamorphosis of exuded products.

Two important factors are then to be considered as the causation of phthisis—i.e.:

1st. The presence of the tubercle bacilli within the cell tissues.
2d. The resisting power of the organism to its growth.

Treatment may then be carried on in either one of two ways, or both.

1st. By attacking the tubercle bacilli within the organism, thus to weaken and destroy.

2d. By promoting the general nutrition.

After reviewing the history and clinical records of phthisis, we are compelled to admit that the greater success has attended the strengthening and fortifying plan.

A study of the animal organism in health reveals the fact that some of the body fluids are acid while others are alkaline, and in disease we find the reactions become altered or reversed; hence, the functions are changed. So, when the reaction of the secretions and excretions become altered or reversed, it is evidence of perverted functions. It will suffice to speak of only a few of the changes that occur in the chemical reaction of the body fluids in disease. The reaction of the saliva in the healthy subject is distinctly alkaline, but in certain diseases it becomes acid; and the normal reaction of the gastric juice is acid, which may increase until it becomes what is known as hyperacidity, or it may decrease until the acid reaction is absent.

These extreme reactions are of the highest clinical significance; and, on the other hand, there can be but little doubt that equally great changes take place in the cell tissues as are known to take place in the fluids. Hence at times the human organism undergoes changes which favor the reception and growth of the tubercle bacilli.

In the healthy subject we find a certain sanitary condition of the fluids and tissue cells which resists the growth of the tubercle bacilli, and, being unable to thrive, they die within the organism. But in the hereditary subject we find a different condition, where a change takes place; the cells being unable to resist the invasion of the tubercle bacilli, they thrive and grow.

The nutrition of the patient should be promoted by suitable food given in such quantities as to secure assimilation and digestion. In cases unattended with symptoms of indigestion it is well to allow them to take such food as they would in health, not restricting them to any particular kind of diet, unless it is to increase nitrogenous and fatty foods, especially encouraging them to eat plentifully of butter and drink unsparsingly of cream, at the same time diminishing carbohydrates, which patients do not digest well.

A very large percentage of phthisical patients present symptoms of indigestion, which makes their management difficult and often unsatisfactory, they being unable to take food in quantity sufficient to promote nutrition. In these cases some advocate "forced feeding." But how these patients, whose digestive systems are already deranged, can take, digest, and assimilate more food than is desired, I certainly fail to understand. It seems to me more rational to restrict the diet in cases with impaired or deranged digestion to liquids of an easily digestible nature, until such a time as the gastric functions are restored, and then from time to time add such articles of diet as are found to agree with the patient. It is difficult to formulate a rule for feeding phthisical patients. The satisfactory thing to do is to carefully study each case separately, and adapt the diet to the individual ease.

I would warn against the pernicious habit of giving patients something to eat between meals, unless it is a glass of hot milk.

The surroundings of the patient should be such as to favor nutrition: the dwelling located in a region known for its purity of atmosphere, where there is freedom from all miasmatic and malarial influences; if possible, where the extremes of temperature are not too pronounced. The site should be a pleasant one, with southern exposure and protected from cold winds. Drainage should be as perfect as it is possible to make it; the house should be well ventilated and lighted. Dampness is conducive to the growth of the tubercle bacilli as well as other germs.

One great difficulty confronts us in the treatment of these cases, and that is, to get the patient to consent to a plentiful supply of fresh air in the sleeping room. It is too much the habit for people to shut out the good fresh air, which is so essential. The sleeping room should contain but little furniture and the bed clothing should be woolen. It is well to cover the floor with a rug that can be removed and cleaned at pleasure; the walls and furniture of the room should be mopped weekly with a solution of mercury bichloride (one in a thousand). Sweeping or raising a dust is very dangerous, and should be strictly forbidden.

A sponge bath should be taken every morning in the following manner:

The patient standing in a tub that contains a few inches of warm water, just enough to cover the feet, so that they may be kept warm until dressed. Beside the patient, on a stand, should be a basin of cold water, about 50° to 65° F., and a large sponge. With this sponge, lightly wrung out of the cold water, the entire body should be gone over rapidly; then, dipping the sponge in the cold water again, it should be squeezed over the shoulders and chest. After rapidly drying
with a coarse Turkish towel the patient should be dressed, still keeping the feet immersed in the tub of warm water. If the morning baths are carried out in this manner they will be found very refreshing and invigorating.

The patient should wear woollen underwear the whole year, but of different weights for different seasons: a heavy weight for winter, a medium weight for spring and fall, and for summer a light merino.

If proper precautions are taken regarding the underclothing, we need not bother much about the outside clothing, as common sense will no doubt dictate to the patients proper changes, according to the weather.

A most important feature regarding the prophylaxis of tuberculosis, so far as it relates to destroying the vitality of the bacillus outside of the human body and to minimizing the sources of infection, is the care and proper disposition of the expectoration and other secretions which might contain the bacilli.

A number of distinguished members of the medical profession have expressed their views as being favorable to the isolation of consumptives, but I cannot permit this opportunity to pass without placing myself on record as utterly opposed to any such measures. Isolation had been practised long before Koch demonstrated the bacillus of tuberculosis. In Naples and in Portugal laws existed a hundred years ago which placed consumption upon the same footing with pestilence and smallpox. The laws in Naples were of the most stringent character, and existed in the same form for about fifty-four years without affecting the prevalence of consumption to any marked degree. If the advocates of isolation would reflect for a short time and consider the hardship and injury which would follow its introduction, affecting, as it would, a large proportion of the human race, and seriously interfering with our entire social life, without giving the slightest assurance of better results than those obtained after many years of trial in Naples and Portugal, one would think that they would hesitate to advocate so inhuman a proposition. It can not be denied by them that a very large proportion of consumptives are phthisical subjects long before they themselves are aware of it; and even physicians frequently treat "alveolar catarrh" as bronchitis until the microscope demonstrates the fact that the patient's expectoration is full of tubercle bacilli. What benefit would be derived by isolating advanced cases of pulmonary consumption if in the early stages they are permitted to deposit millions of microbes with their expectoration upon the public streets, in public places and conveyances, and in their own homes; and, finally, what advantage would isolation have if carried out in New York State and not in New Jersey, or if adopted in the United States and not in Canada? Isolation is not only cruel, but it is entirely infeasible, and the sooner the medical mind is directed in other channels the better it will be. Patients should be well instructed that to expectorate in any place except in the proper receptacle means great danger to themselves and others.

The receptacle for expectoration should be half filled with an antiseptic solution, and have a tight-fitting cover, that it may be closed when not in use, so flies may not gather about it. I caught a few flies in my hand that were gathered about a spittoon in the room of a phthisical patient, and, taking my captives to the laboratory, prepared, stained, and mounted the tongues and feet. Upon microscopic examination of these specimens I found millions of tubere bacilli, thus proving the fly to be a germin carrier and a very dangerous source of infection. These same flies could have entered the kitchen or the dining room, alighted upon the prepared food, dropped into the milk, or got into the butter, and so infected those that partook.

Cornet says that he "obtained the dust from the walls of a room occupied by a consumptive. This dust was made into a broth, some of which was injected into several animals, all dying within a short time of typical bacular tuberculosis."

Experiments show that dried sputum inhaled is a common source of infection. Patients in bed and too weak to make use of a spittoon should be provided with moist rags, which should be burned immediately after use. The infectious nature of the saliva should be a warning never to kiss.

The question of inheritance has always been considered one of vital importance among those interested in the study of pulmonary consumption. The views now generally held deny the existence of congenital tuberculosis; but the disposition to acquire the disease is most commonly found among the offspring of consumptive parents, and about one third of all phthisical patients come from either paternal or maternal parents suffering from consumption. Diligent inquiries into the family histories of many consumptives induced the writer to make the following statement:

Only a small proportion of phthisical patients can be found who do not possess a family history which either demonstrates a directly inherited tendency or a directly or indirectly acquired disposition toward the development of the disease.

If a climate is to be at all beneficial it is in the early stages, occurring in persons capable of taking active exercise. The disease should be limited, non-progressive, and quiescent, or but slowly advancing, with little or no fever. It is a mistaken idea to send patients that are advanced into the second and third stages of the disease off on a globe trot when rest and home comforts are in greater demand. I do not believe in the specific curative quality of any climate, but do believe very strongly that it is essential to the majority of phthisical patients to be treated and cured in the same climate that they have to live and work in after their restoration to health. The features of "consumptive resorts" are greatly overestimated and dangerous. Asheville,
North Carolina, is no exception. Having lived there and devoted much time and study to the subject of tuberculosis, also being associated with an esteemed and valued friend, Professor Edwin Klebs, I feel that my opinion may be of some value. Asheville, North Carolina, is a city where thousands of phthisical patients gather from all over the country, the majority being in the second and third stages of the disease. These poor, misled patients are advised to go to Asheville, because "a change of climate will cure them," and so they make every effort possible to reach that haven; and the home physician draws a sigh of relief when they have gone. And so the patient arrives in Asheville to find thousands there for the same purpose—i.e., "to be cured without physician's aid, as climate will do it all."

Here we find thousands without a medical adviser, going about the city streets, depositing expectoration that contains millions of tubercle bacilli upon the sidewalks every few feet, which, being exposed to the sun's rays, dry and pass off into the atmosphere, to be inhaled into the air-passages of the inhabitants. Flies alight upon these deposits of expectoration and then go from dinner table to dinner table, drop into the milk, alight upon prepared food, and so infect the masses. Such a state of affairs is most dangerous, and the profession should know the condition, that they may govern themselves accordingly.

It is no single remedy or climate that is a panacea against phthisis, but it is a judicious and continuous application of a great number of differing influences and remedies fitting to the individual case which promises good results. Patients, as a rule, do not know what will help or injure them. They require constant care and comfort. The diet must be adjusted to the present powers of digestion. Many patients, when improved and on a fair way to recovery, suffer a relapse from various causes of indiscretion and overexercise caused by ignorance or want of self-control. Consumptives are, in many respects, a peculiar class of people. The hopefulness which is a part of their disposition almost always accompanies the disease and leads them to regard many indications of failing health with indifference, no matter how self-evident these may be to their relatives and friends. They feel out of sorts, experience a constant tiredness, are perhaps a little more irritable than formerly, and many times complain of an impaired or capricious appetite; they lose in weight, become a little feverish in the afternoon or evening, have a slight cough and expectoration, and pass restless and dreamy nights, due to sweating and high temperature; yet none of these symptoms seem to draw their attention to themselves, until, greatly to their surprise, they are suddenly seized with the spitting of blood. No matter how small the amount may be that is brought up, there is nothing that will alarm or demoralize a patient more than this. They seek medical relief without delay, and seem to realize their condition from this moment.

This is one kind of haemoptysis which comes under observation. Then we have another, which occurs in the following manner: A patient may or may not have slight spitting of blood, going through the various stages of the disease, to the point of excavation, without any recurrence of this trouble: but, all at once, without any warning or apparent reason, he is seized with a violent hemorrhage, blood gushing out of the nose and mouth, seemingly to be in imminent danger of bleeding to death; and, indeed, death does result from such a hemorrhage, this condition being caused by a rupture of a vessel in a cavity.

The condition of the first class of patients mentioned (blood-spitting) emanates from the rupture of the bronchial or pulmonary capillaries, also from extravasation or oozing of blood through and from the walls of the blood-vessels. That of the second class comes from a break in the walls of an exposed and unsupported aneurysmal artery on the surface of a cavity. The difference between these two types mainly consists in the amount of blood which is lost and the ease or difficulty with which the blood flow can be checked. Practically, the first deals with those patients who have no cavity, and, so to speak, are in the first stage of the disease; while the second comprises those which have a cavity, and are therefore in the third stage of tuberculosis.

The first aim in the treatment of all cases of haemoptysis is to make the patients comfortable, both physically and mentally. Place them at rest upon the back, and administer morphine and atropine hypodermically. If the bleeding does not come from a cavity, or is not too copious, assure them that in reality the hemorrhage has no serious significance; that the bleeding is indeed not only harmless, but an actual benefit, since it unloads and relieves the congested condition of the affected area. This will tend to allay fear and nervousness more than anything else. If you succeed in doing that, you will have gained a most important point in the management of the case. The patient should be kept quiet and in bed, and under no condition allow him to sit up until forty-eight hours have elapsed since the last trace of blood was seen. In all cases of profuse hemorrhage the patient must be made to cough up the blood, so that it may not congregate in the air-passages and cause death. In some cases without a cavity, the haemoptysis is quite copious, and medical treatment internally is unable to subdue it. Under these circumstances resort must be had to local application of ice to the patient's chest. This is well done by filling one, two, or three rubber bags with ice, which should be wrapped in towels and brought in contact with the skin; by this means the bleeding is usually controlled in a short time. There is a certain amount of unnecessary fear and prejudice against the use of the ice-bag which prevents its application and fosters the idea that it should be held as a last resort. This is a serious mis-
take and should be corrected. If the haemorrhage is at all profuse, apply the ice-bag without delay. Sudden atmospheric changes in the rise and fall of the barometer seemingly influence pulmonary haemorrhage.

There is no doubt that the phenol group has a larger field than is yet developed. Recent investigations confirm us in the conclusion that the wider the scope of the drug the more it emphasizes the value of the treatment we put forward. Guaiacol is recognized as the most efficient agent that we possess for the treatment of tuberculosis. It should be given in small doses at first, and gradually increased, going from one to fifteen grains at a dose. The therapeutic value of guaiacol is an established fact, and proof is not wanting. Its germicidal qualities and its ability to repair tissue waste and increase the red blood-corpuscles and hemoglobin make it an essential element in the modern treatment of phthisis. Guaiacol in large doses certainly has caustic properties, and not only burns the mucous membrane, but destroys the epithelium of the gastric tract, and, for this reason, it should be given only in small doses, the effects of which will be found pleasing and highly satisfactory. A tablespoonful of emulsio sevi et olei comp. (Dr. Russell), in a glass of hot water after meals, will be found a very valuable aid in the repair of tissue waste.

With knowledge of digestion and body requirements, a more perfect grip of essential wants of the phthisical, and the importance of arresting all outgoings, as well as the introduction of food at once digestible and nutritive, the prospects of the phthisical are much brighter than ever before. Phthisis and gastric derangement go hand in hand, and malnutrition adds to the rapid downfall of a struggling constitution. The symptoms which furnish therapeutic indications are cough, pains in the chest, fever, and dyspnœa. Coughing, to some extent, is necessary for the removal of morbid products within the bronchial tubes and cavitie{s, but in those cases where the cough becomes excessive phenobromate in five-grain doses every hour will give much relief. Pains in the chest, whether due to neuralgia or pleurisy, will be relieved by one or two ten-grain doses of phenobromate. For patients whose fever does not go higher than 100° F. a cold sponge bath under the bed clothing will be found most beneficial. Should the temperature go up soon after, phenobromate in five-grain doses will be of good service.

Phenobromate is an analgetie and antipyretic of coal-tar origin, being a superior preparation to antipyrene or phenacetin, acting chiefly on the thermotactic centre, and, to a slight degree, on the skin, increasing elimination, and as a hypnotic in this class of patients it will be found excellent. Phenobromate is not destructive to the corpuscular elements of the blood, and possesses the advantage of being a prompt antipyretic as well as an analgetic preparation. It does not depress the circulation, and may be given in large doses for many consecutive weeks without the slightest danger of ill effects.

In all patients who have made an apparent recovery, and in whom the disease has been arrested, it is well to dwell on the importance of using a clinical thermometer several times daily for at least a year, and in the event of fever they should report to their physician. The necessity for this precaution is obvious when we reflect that many of the germs of tuberculosis continue to live, though in a quiescent state, for an undetermined period after all manifestations of their presence have ceased, and then, so long as this condition obtains, fever of any kind, if not promptly checked, could easily awaken them to renewed activity, whereas, if fever is kept down continuously, they will remain weak and impotent; hence the germ-destroying forces of the body will ultimately destroy them.

397 Third Street.

'THE TERM APPENDICITIS, ETC.

By R. ELLIS, M.D.,

I have read the article on The Term Appendicitis, and Other Unscientific Words of our Nomenclature, which appeared in your issue of May 20th.

Will you permit me to look over the ground it covers, especially since the article concludes with the statement: "It is positive that our nomenclature, so far as the terms which purport to be Greek are concerned, will remain in gross contradiction to science, so long as malevolence and error in regard to the Greek of today exist among us," a statement that requires an answer after a review of the premises which led up to such a final conclusion?

The author criticises the mongrel word "appendicitis," and he would substitute in its place the pure Greek word—scoleoiditis (σκολοειδής and είτης) because, forsooth, the Greek ending είτης is added to a Latin word, appendix.

Is there any literary rule which absolutely forbids such a formation, if euphony and simplicity are gained? Are we obliged to use words whose parts are derived from one language, if a better word is born by uniting words derived from two languages?

We like the Greek words, perityphilitis and paraphytitis, but we also like the mongrel "appendicitis" just as well. But you say, "It is not a pure word." Well, suppose it isn't; the word means more to me than any word I may form from either the Latin or the Greek. Would any one change that expressive word "appendicitis" for a harsh "scoleoiditis," even though it is "pure Greek"?

Why not accept a pure Latin word, "appendinflammatus"? But as we discuss this mongrel word, other aspiring philologists present their words, so we have this list: appendicitis, scoleoiditis, appendinflam-
natus, ephyaditis, epityphritis, Wurmfortsatzentsün-
dung, perityphritis, etc. Now, that “homely” word
“appendicitis,” mongrel though it is, heads the list as
a euphonious word, exactly expressing what we wish.
Shall we drop the Latin word, and use that disagree-
ably sounding Greek word σκολυκοείδης?

The author speaks of the purity of Greek, the
impurity of modern German, and derides the “Ελληνο-
φανής language,” or the “resembling Greek” language,
“forced upon us by our own highly learned medical
writers,” and decides it is about time we were ashamed
of this “mockery of science.”

Can it be a mockery of science to unite a Latin and
a Greek word if they express more than two Greek
words do?

Certainly the educated mind will prefer the best
word, irrespective of its derivation.

Is not scoleoiditis a better word than appendix-
flamnatus? For the same reason appendicitis is a bet-
ter word than scoleoiditis, even though the Greeks do
use it. The Germans use their Wurmfortsatzent-
zündung and prefer it to our “appendicitis,” but we
never expect to adopt their word.

We must grant it is advisable to use pure Greek in
our new technical words, if we can at the same time
obtain the most expressive word, especially since most
of our technical words are Greek—as purely Greek as
though they had been formed by Greek physicians in
Athens. We grant it would be better to substitute
even a scoleoiditis for a Wurmfortsatzentzündung, es-
pecially if we are to attend lectures in Berlin or Vienna.
Having had such an experience, we are sure we favor
correctly formed Greek words—yes, and only Greek
words—for technical description, in order to make the
scientific terms “international,” and render German
lectures intelligible and international meetings more
satisfactory; but such a nomenclature is an impossi-
ability.

A study of German technical words, beginning
with their labyrinthine word for appendicitis (in which
a man may lose himself and wander for days), will con-
vince any physician that the profession of Germany has
followed the new version of the golden rule, “Do to the
other fellow what you think he’s going to do to you,
but do it first”—in other words, the German has done
what he feared the other fellow would do for him—he
has filled his medical lexicon with his own words rather
than accept them from “the other fellow”; he revels
and frisks in and around these words, though they are
impassable fortresses to an outsider. Certainly the
German prefers his own words to the international
words of “the other fellow,” so that his medical
words are as firmly fixed and as immovable as our own
appendicitis, which is as securely immovable as are the
pyramids of Egypt, and can never be “purged” from
our nomenclature, not even by a strong Greek cathartic.

We grant there is an international advantage in Greek
words, especially if we could at once wipe out of our
brains all national medical words and replace them by
international words; but, alas! it is so hard to acquire
even an imperfect nomenclature that we can not “let
go” easily, and catch on to substitute words, especially
if the author begins by taking away from us policlinic
and substituting astyclinic!

Before he definitely decides to give us this better
word, this astyclinic, would it not be well for him to
again consult his ever-unchanging Greek lexicon? As-
yclinic for our beloved policlinic!

Why, ἀστυν means the real town itself, as distinct
from its port or its outlying districts; so we have ἀστυν
τὴς πόλεως! ἀστυν, a name going back to the Sanskrit vās,
—to dwell, from which we have ἀστυν and the Latin
Vesta. Is it for this reason the author gives us astyclinic,
keeping in mind the ἀστυν τῆς πόλεως? But what’s the
matter with policlinic, especially since an Irishman in
the vicinity of Thirty-fourth Street and Third Avenue
would be mobbed and possibly killed if he said he was
going to the “astyclinic”!

Policlinic! dear old policlinic! must we give up
even thee, pure Greek as thou art?

No, indeed; not so long as we have a Greek lexicon.
We brush away the dust and rush to thy assistance,
dear old policlinic, or even polyclinic!

Now, then, πώλας is an Homeric word, applied to the
fort of a city, or to the whole city, or even to the entire
city, including the country about the city as dependent
in many ways upon the city.

This use is seen in the writings of Homer, Hesiod,
and Sophocles. Witness the expression δήμος τε πώλας τε,
where πώλας denotes the entire city—in fact, πώλας, mean-
ing city, is used more often than ἀστυν by every classical
author; yet our learned author would, πρὸς τῷ ωθίων, change policlinic to astyclinic! Certainly, we can
never improve medical nomenclature if we begin in this
way. Our author would change the barbaric vaginismus
to coleospasmus; vaginitis to colpitis; pathology to
nosology. The author then criticises pathogenesis (a
correct word, πάθωσ-γένεσις) as follows: “On the first
page of the text-book of Niemeyer we find the word
‘pathogenic.’ Now, if we knew everything that we don’t
know, we might perhaps allow the word to pass,
although, used in the sense in which it is intended in
Niemeyer’s book, it would have no sense after all. In
the Greek books of to-day it reads γένεσις τής νόσου.
Pathogenesis as a word can not be found in any Greek
lexicon.” Shades of Zeus, Hippocrates, and Hera, must
we limit ourselves to words found in the Greek lexicon,
when we can at once form such an expressive new word
as pathogenesis, which is pure Greek, and so much
more terse than γένεσις τῆς νόσου? Truly, the Greek
language has been kept so pure that a scientific man
does not need the classic atmosphere of Athens to breed
a Greek word—nay, verily, in his study in Berlin, New
York, or London, the student can correctly form new
Greek words, especially if the Greek language does not contain exactly what he seeks—euphonious sound to convey exact meaning.

So any student anywhere can breed in his brain a word (that may represent unceasing investigation) and present it to scientific society. If it is needed, the word becomes a part of ever-growing, ever-dying scientific language.

We agree with the author that it is “horrid” to call the cardiae orifice of the stomach “cardia,” and to call stomach pains cardialgia, yet these unusual words are but as weeds in a garden of beautiful flowers, and weeds will insist on appearing occasionally; even the immortal Virgil wrote of “plowing the salt with the bronze,” a synecdochial use of language which explains cardialgia and cardia, “the object near for the object itself”—surely another case of a lucus e non lucendo. The originator of these mongrel words never heard of the principle Ne sutor ultra crepidam, and so we forgive him.

Likewise the Germans have named a supposed symptom of hydrophobia—Wasserscheu—for the disease itself, and some careless student translated this into the equivalent Greek—hydrophobia—a symptom name which is firmly fixed as a name for dog madness—a name that will endure as long as men love dogs and dogs “go mad.”

Of course we don’t expect to find the word hydrophobia in a Greek lexicon as an equivalent to lyssa, but why not coin a better word than lyssa? Why not the word cynomania (κύων and μάυρα)? Surely a better word, when we realize lyssa in Homer means “martial rage,” and then later “raging madness, especially caused by the gods” (as the insanity of Orestes over killing his mother), and again “Bacchic frenzy,” and again personified into the goddess of insanity, Αἰδώρα. Thus having made the rounds, it was used by Xenophon to mean dog madness.

Why not improve upon the general term lyssa by the special word, exact in meaning, “cynomania”? But, you say, “There is no such word in the Greek lexicon!” My reply is, “Let us put it there to improve the lexicon.”

Now the author quotes a German philologist, an “exceptional” man, who believes that future barbarisms can be avoided by establishing at Athens an academy to pass judgment upon technical medical terms, and thus prepare the way for a perfect international nomenclature—an object to be desired almost as much as an international language of science, and almost as impossible of attainment.

This German philologist (dear old fellow, I see him now with his pipe and Stein) complains that “the chemists with their terrible [I see him drain his Stein] new formations of word monsters are much worse than the physicians.” I am glad he said that.

The author concludes his article by the following, part of which I quoted at the beginning of this article: “Chemistry and medicine are not scientific so long as they teach something which has proved to be false, which is unscientific; and false and unscientific is the medical technical language employed by us this very day. It is positive that our nomenclature, so far as the terms which purport to be Greek are concerned, will remain in gross contradiction to science so long as malevolence and error in regard to the Greek of to-day exist among us.”

Such a conclusion requires a very short answer:

1. If all technical chemical and medical words were mongrel words like appendicitis and anthropometalism, the science would remain the same, in spite of poorly selected words, just as broken English may express exactly the thought of pure English, even though it may be harder to understand.

2. The author makes an absurd mistake in supposing there is “malevolence and error” in regard to the Greek of to-day.

In conclusion, an international, or even a national, pure nomenclature is an impossibility; it is and has been among the inalienable rights of man to coin new words—such a right is almost included in the right to the “pursuit of happiness”—but no right to “force” a word into use is given any one; we can and we do refuse to use many, many words, since not only are the words poor, but what they represent is of no value to any one.

The result of this “literary survival of the fittest” is that the new words that we really need are presented by men whose knowledge of word formation is such that they are able to offer words beyond criticism; though they are not capable of “Sprachgefuhl,” they certainly are so sprachgelehr that no Sprachgemisch is observed even by the most critical. By an unwritten law, man’s effort in all directions struggles toward a perfection which is possible only at infinity. Medical nomenclature, by this law, will grow more and more pure, but it will take along the needed impure words as old scars and fresh wounds received in the long and inevitable struggle.

WHY FUMIGATION OF APARTMENTS OCCUPIED BY TUBERCULOUS PATIENTS AT HEALTH RESORTS SHOULD BE UNDER MUNICIPAL CONTROL.*

By CHARLES F. McGAHAi, M. D., AIKEN, S. C.

In bringing this subject to your notice I fear some of you will think that I am speaking on a theme that has been fully discussed before, action having been taken upon it by the boards of health of several large cities, as New York and Philadelphia; but it is just

* Read before the American Climatological Association at its annual meeting, held in New York, May 9, 1899.
for this reason that I want the members of this society to realize the dangers to which their patients are exposed when they send them to the so-called health resorts of this country. I claim it is imperative that every health resort where we send our patients should compel the fumigation of apartments occupied by tuberculous patients to be done under the auspices of the sanitary authorities.

I have seen apartments in which have been the worst cases of phthisis disinfected in the most superficial manner, and I have almost shuddered a few days later, when called to these same rooms, to see a case which was showing only the first symptoms of phthisis. Knowing these rooms must be reeking with the tubercle bacilli, I would insist upon the immediate removal of my patient to more hygienic quarters; but there are many cases that take apartments without consulting the physician for some weeks or months, and by that time they would have given the germs every opportunity to contaminate the system. We have some landlords and boarding-house keepers who attempt the disinfection of a room, but, from ignorance of the methods of doing it properly, simply make a farce of it, and at the same time announce that it is perfectly healthy, as everything has been thoroughly fumigated. I remember once having my attention called to a room that was being fumigated; the landlord had carefully pasted paper over all the cracks and keyhole, but had forgotten to close the transom.

Now, if we are so careful at home to have our patients avoid all source of contamination and self-inoculation we should be equally as cautious in selecting a location for them in which to spend the summer and winter, and prevent them from visiting places where the rooms of the hotels and boarding-houses are teeming with tubercle bacilli. Sanitation in most of the small towns of the interior is carried out in its crudest form, and since the contagiousness of tuberculosis has been proved, and the opinion of the profession in regard to it is so well known by most of the laity, we find the larger and better class of hotels at the different resorts refusing to take tuberculous patients; hence it forces that class of patients into apartments owned by people who either do not believe in the contagiousness of the disease or are simply trying to obtain what remuneration they can for their rooms, and in both cases the disinfection is insufficient. Every room offered for rent at a resort frequented by tuberculous patients should have a certificate attached to it stating it to have been thoroughly disinfected and inspected under the auspices of the board of health or sanitary inspector, and that it is, in the opinion of the said board, perfectly healthful. Then we should advise that the local health authorities should pass suitable ordinances by which they can control the nuisance of expectoration on the streets and in the parks; also to regulate the laundering of clothes of tuberculous patients, which should be washed apart from those of healthy people. I consider it our duty as a society to exert our influence to compel the authorities at the different resorts to pass the proper ordinances to protect the patients we send to those places from the avoidable dangers of contagion. We should insist upon their preventing expectoration on the ground, and we should force them to prohibit the washing of handkerchiefs and cloths upon which the patients have expectorated, and in their place substitute handkerchiefs of cheese cloth, to be immediately burned after use.

In my small sanitarium in Aiken I have enforced the strictest sanitary measures, and am pleased to say that I have so instructed the patients in regard to the laws of hygiene that they consider it necessary to conduct themselves as educators to the townspeople. We are now introducing a system of sewerage in Aiken which is considered to be the best known in the world for an inland town, and is the one so successfully experimented with by the Massachusetts State Board of Health and adopted by them in preference to all others for their interior towns.

The perfecting of the sanitation of Aiken will make the town as conducive to the promotion of health as any resort of the kind I know of, especially since this last improvement is but another advantage added to the superior features of climate and hygiene with which Nature has so richly endowed this little town among the pines of the southland.

In conclusion, I beg to add the hope that I have the hearty cooperation of this society in furthering the adoption of the idea herein mentioned.

Therapeutical Notes.

An Application for Acne.—The Indépendance médicale for May 3d gives the following formula:

R. Precipitated calomel ................. 5 parts;
Glycerin .................................. 30 "
Camphorated spirit ....................... 80 "

M.

An Emulsion of Cod-liver Oil.—The Reforma medica for April 29th gives the following formula:

R. Cod-liver oil ......................... 500 parts;
Sugar ................................... 190 "
Gum arabic .............................. 5 "
Gum tragacanth .......................... 500 "
Infusion of coffee ...................... 200 "
Rum or kirsch .......................... 100 "

M.

For Facial Pains from Carious Teeth.—Dr. Leo Greenbaum (International Dental Journal, May) recommends:

R. Acetanilide ........................... 8 grains;
Phenacetine, \[
\begin{align*}
\text{Citrate of caffeine,} & \\
\end{align*}
\]
of each .... 15 "

M. To make eight powders. One to be taken every two hours.
THE NEW YORK MEDICAL JOURNAL.
A Weekly Review of Medicine.
Published by D. APPLETON AND COMPANY
Edited by FRANK P. FOSTER, M.D.

NEW YORK, SATURDAY, JULY 15, 1899.

THE CHICAGO BOARD OF HEALTH AS AN EDUCATING AGENCY.

We have often commended the sanitary work and the investigations of the Chicago board of health, and it is with great satisfaction that we now learn, by a circular, dated July 1st, issued by the commissioner of health, Dr. Arthur R. Reynolds, that the board is prepared to give practical instruction to young men in sanitary science and public hygiene. No fees are to be charged for any of the courses; even instruments, reagents, and other necessary appliances will be furnished gratis. Only graduates in medicine and senior undergraduates of reputable medical schools will be eligible as "internes" in the laboratory, and all applicants will be required to pass an examination in physics, chemistry, bacteriology, and biology.

"The term 'instruction,'" says the circular, "implies the actual doing of every detail of the work in each course by the student himself." The graduate pupils will work three hours daily for two weeks in each of the following courses: General bacteriological work; the bacteriological diagnosis of disease; the chemical analysis of water, ice, and articles of food; and bacteriological examinations of such substances, with special chemical and bacteriological work in the examination of milk. The term of instruction, therefore, will comprise eight weeks, and at its termination each pupil whose work has been satisfactory will receive from the commissioner of health a certificate of his attendance and qualifications.

Undergraduates who have passed the sophomore year will be required to work for a term of only four weeks, attending three hours daily and doing such work as may be assigned to them in preparing culture media, putting up culture outfits, incubating, sterilizing, taking care of instruments, fitting and constructing apparatus, etc., in short, doing the elementary practical work in bacteriology and sanitary chemistry and assisting their teachers. At the close of the term the pupil will receive a provisional certificate entitling him to admission to the senior course without further examination.

In addition, there are to be a special course in sanitary inspection, lasting four weeks, during the first half of which the pupil will accompany a sanitary inspector in his daily work, and during the second half of which, if he has shown sufficient ability, he will take assignments, make inspections and reports, and in fact act as a sanitary inspector on his own account; a two weeks' course in vital statistics, embracing the nomenclature and classification of diseases for statistical purposes, the computation and graphical representation of statistical results, and the laws and ordinances relating to the disposal of the dead; and a course in the department's methods of dealing with infectious diseases, including notification requirements, the isolation of patients, prophylaxis, vaccination, the use of diphtheria antitoxine, formaldehyde disinfection, etc.

Surely this is a scheme well calculated to bring additional credit to a board that has already won enviable laurels. So far as we know, it is the first of the kind to be undertaken by an American health board, at least on so comprehensive a scale and with such generosity toward the pupils. We hope the Chicago board's example will be followed widely.

THE NOMENCLATURE OF "PSEUDO-TUBERCULOSIS."

We have been favored with a copy of the Report of the Committee of the Pathological Society of London Appointed to Consider the Nomenclature of the Conditions sometimes described as Pseudo-tuberculosis. The committee consisted of Dr. J. F. Payne (chairman), Dr. J. McFadyean, Dr. S. G. Shattock, Dr. J. W. Washbourn, Dr. G. Sims Woodhead, and Dr. A. G. R. Foulerton (secretary), and the report is dated May 6th. The morbid conditions considered by the committee included nine varieties of infection with various bacilli and cocci, as exemplified in cases described by Du Cazal and Vaillard in 1891, by Malassez and Vignal in 1883 (of a form similar to that recorded by Chantemesse in 1887), by Eberth, Nocard, Zagiari, and Parietti in 1885, 1889, and 1890, by Nocard (as occurring in fowls) in 1885, by Eberth, Charrin and Roger, Dor, and Legrain (as occurring in rodents) in 1885, 1888, and 1891, by Courmont and Nuvoletti (as occurring in bovine animals) in 1889 and 1894, by Pfleiffer (as occurring in horses) in 1889, by Kutscher (as occurring in mice) in 1889, by Preiss and Guinard, Preiss and Morey, and Tursky (as occurring in sheep) in 1891, 1893, and 1897, and by Galli, Turni, and Deleidi (as occurring in swine) in 1896: blastomyxosis, causing the "pseudo-lupus vulgaris" of Gilechrist and Stokes; streptotrichosis, including Eppinger's pseudo-tuberculosis.
EDITORIAL ARTICLES.

July 15, 1899.

A THEORY OF THE DELAYED MANIFESTATIONS OF CONGENITAL SYPHILIS.

What seems to us an attractive piece of theorizing is set forth in a paper entitled Congenital Syphilis: a New Theory, by Mr. Campbell Williams, F. R. C. S., read before the Dermatological Society of Great Britain and Ireland last November and published in the February number of the British Journal of Dermatology. Mr. Williams divides congenital syphilis into four degrees of virulence, the first characterized by the early death of the foetus and its expulsion by abortion, the second by the birth of the foetus, alive or dead, at or near term, with syphilitic manifestations on its body, the third by the appearance of such manifestations almost immediately after birth, and the fourth by the intervention of a period of apparent health between the child’s birth and the occurrence of signs of syphilis, a period about equal in duration to the ordinary incubation stage of the acquired disease. These four degrees, he remarks, are directly proportionate to the severity of the disease in the mother.

It is with his fourth degree of virulence that he deals more particularly, and it is observed, he says, in infants whose mothers have shown during the gestation no pronounced signs of syphilis, but only marks of ill health that might well be accounted for on some other ground, but that, nevertheless, yield remarkably to mercurial treatment. Such women, he thinks, have received their contamination either from men whose disease is mild but of recent acquisition or from men in whom it is of many years’ duration. The mildness of the affection in the mother he attributes to the production of an antitoxine in her blood, and, considering the mother and the foetus in utero as one organism, so far as the circulation is concerned, he conceives that the foetus shares in its beneficial action, but, being deprived of the maternal supply by being born, the child fails to produce it for itself, and falls a prey to an infection which had previously been held under control, while the mother goes on producing the protective substance and remains free from syphilis of a pronounced type.

Mr. Williams recognizes that we do not yet know positively that syphilis is the work of a living, self-multiplying micro-organism, but he evidently has little if any doubt that such is the case, and probably in this the profession in general agree with him. His theory must certainly rest on an assumption of the germ doctrine of the aetiology of the disease.

INTRA-UTERINE INJECTIONS AND EXTRA-UTERINE PREGNANCY.

The view taken by Professor E. F. Fabbri (Atti della Società italiana di ostetricia e ginecologia, 1898; Gazzetta medica lombarda, May 29, 1899) that in a case of tubal gestation observed by him the arrest of the ovum in the Fallopian tube was due to the use of intra-uterine injections seems not unreasonable. His theory is that they aggravated the normal changes in the tube incident to gestation and set up a catarrh which was instrumental in retaining the ovum.

THE VERRUGAS OF PERU.

This curious affection, also known as Carrion’s disease, after a luckless young physician who lost his life in consequence of having inoculated himself with it, has been made the subject of a monograph by Dr. E. Odriozola. The author thinks malarial parasites are found only in cases in which there are malarial complications, but a reviewer in the Centralblatt für innere Medizin for June 17th, Dr. Schenebe, of Greiz, thinks there is a closer connection than this between malaria.
and verrugas. Dr. Maurice Letulle, who did the historical part of Odriozola's work, found, together with ordinary pyogenic cocci, bacilli resembling those of tuberculosis, and perhaps these are the cause of the disease, says Scheube.

**REJUVENESCENCE OF THE HAIR.**

Perhaps the restoration of gray hair to its original color without the use of a dye is as rare as sudden blanching of the hair. Several cases, however, have been reported within the last twenty years, as is shown in the Medical and Surgical Review of Reviews for May. The writer cites Dr. J. Foustanos, the editor of La Grice médicale, as suggesting the following explanation: Pigment is formed in the deep layer of the epidermis all through life, but in old age it fails to be conveyed to the hair; if, however, the capability of transfer is restored, the hair regains its original color. This explanation, it must be confessed, leaves something to be desired.

**"TIRED OVARIAS AND A HUNGRY WOMB."**

We learn from the British Medical Journal for June 17th that the midwives of Manchester and the region round that city have formed a society and issued a volume of Transactions. From this volume our contemporary gives several specimens. In one of them, from a paper entitled Malthusianism, or Tired Ovaries, the author states that the forty-year-old virgin is rarely healthy, and the same is true of the married woman who resolves to have no more than one or two children—they are both afflicted with "tired ovaries," from constant ovulation, and "a hungry womb."

**A MAGISTRATE'S IDEA OF THE DIVISION OF FEES.**

A correspondent whose communication is published in the Gazette hebdomadare de médecine et de chirurgie for April 30th tells of a scandalous decision by a justice of the peace in a suit brought by a physician to recover certain very moderate fees charged by him for assisting at an operation for cataract and for carrying out the after-treatment. A Paris ophthalmologist happened to be at Joigny, where the case occurred, and he performed the operation, took his fee, and departed. The justice ruled that the family physician should have been paid out of that fee, and declared that it was customary in such cases for the operator to give one third of his fee to the physician in charge. It is to be hoped that the tribunal before which the case is to come up again will not only reverse this justice's decision, but rebuke his impudence in assuming to declare what is customary in the practice of medicine.

**THE COMMERCIAL ASPECT OF "CHRISTIAN SCIENCE."**

The Peoria Medical Journal for May reprints the following notice from the Christian Science Sentinel, signed by Mrs. Mary Baker Eddy and dated March 27, 1899: "It is with pleasure I certify that after months of incessant toil and at great expense Mr. Henry P. Moore and Mr. J. C. Derby, of Concord, New Hampshire, have brought out a likeness of me far superior to the one they offered for sale last November. The portrait they have now perfected I cordially endorse. Also I declare their sole right to the making and exclusive sale of the duplicate of said portrait. I simply ask that those who love me purchase this portrait." Our Peoria contemporary calls upon those "who yet think that our 'Christian Science' sisters and brethren are not controlled in their activities by the commercial spirit" to interpret the notice—and well it may.

**"A SPECIES OF KIDNEY TROUBLE."**

One of the newspapers recently spoke of the death of a well-known citizen as having been due to acute nephritis, which he "developed" from chronic nephritis, "a species of kidney trouble." It is marvelous that the writer failed to state what "superinduced" the fatal illness.

**SCARLET FEVER AT WEST POINT.**

Every American citizen who is worthy to be one will feel a pang of regret at learning that the festivities that are annually held at the military academy at this time of the year are likely to be dampened this year by the occurrence of a number of cases of scarlet fever among the cadets and the enlisted men. The outbreak is particularly to be regretted on account of its interfering with the reception that had been planned for the naval cadets.

**THE "KISSING BUG."**

For a number of days past the newspapers have busied themselves with chronicling the dire work imputed to an insect which, being not yet identified by the entomologists, is popularly spoken of as the "kissing bug," from its predilection for the lips of its human victims. Its bite or sting seems to be productive of unusually severe phlegmonous inflammation.

**THE TRANSPORT McCLELLAN.**

It is very gratifying to learn that the yellow-fever patients on board the transport McClellan, which has been detained in quarantine for more than a week, are convalescent. This result will doubtless much encourage the health officer, Dr. Doty, in the use of the anti-toxin that has been employed in these cases.

**ITEMS.**

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 8, 1899:

**Change of Address.**—Dr. V. A. Robertson, to No. 831 Union Street, Brooklyn.

**Army Intelligence.**—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 1 to July 8, 1899:

**Gibson, Robert J.** Major and Surgeon, will report to the chief surgeon for temporary duty during the absence of Raymond, Thomas U., Captain and Assistant Surgeon. Major Gibson will take station temporarily in San Francisco.

**Girard, Alfred C.** Major and Surgeon, is assigned to the command of the new general hospital, Presidio of San Francisco, and, in addition, he will take command of the old general hospital at that post, relieving Matthews, W. S. H., Major and Brigade Surgeon, United States Volunteers.

**Howard, Deane C.** Captain and Assistant Surgeon, is detailed temporarily as a member of the army retiring board ordered to meet at Governor’s Island, New York, during the absence of Byrne, Charles C., Colonel and Assistant Surgeon-General, temporarily relieved.

**Kennedy, James M.** Captain and Assistant Surgeon will, on account of illness, remain at the Presidio, San Francisco, for temporary duty.

The following officers of the medical department will report to San Francisco for assignment to temporary duty: Flagg, E. B., Captain and Assistant Surgeon; Dutcher, Basil H., First Lieutenant and Assistant Surgeon; Dean, Elmer A., First Lieutenant and Assistant Surgeon; Greenleaf, Henry S., First Lieutenant and Assistant Surgeon; Rash, Otway W., First Lieutenant and Assistant Surgeon.

Matthews, Willard S. H., Major and Surgeon, United States Volunteers, will proceed to Manila.

**Naval Intelligence.**—Official List of Changes in the Medical Corps of the United States Navy for the Week ending July 8, 1899:

**Plummer, Ralph W.** Assistant Surgeon. Appointed Assistant Surgeon from June 17, 1899.

**Wise, J. C.** Medical Inspector. Granted leave of absence for three months on account of sickness.

**Marine-Hospital Service.**—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending July 6, 1899:

**Murray, R. D.** Surgeon. To defer departure to Key West, Florida (as directed by bureau letter of May 15, 1899), until further orders, and to proceed to New Orleans, Louisiana, for special temporary duty.

**Wadson, Eugene** Surgeon. To proceed to Norfolk, Virginia, and assume temporary charge of the service at that port not later than July 17, 1899.
McAdam, W. R., Assistant Surgeon. Bureau letter of May 15, 1899, relieving Assistant Surgeon McAdam from duty at Key West, Florida, revoked and directed to reassume command of the service at Key West.

Robinson, D. E., Assistant Surgeon. Relieved from duty at Chicago, Illinois, and directed to proceed to Mobile, Alabama, and report to the commanding officer for duty and assignment to quarters.

Altree, G. H., Acting Assistant Surgeon. Granted leave of absence for four days.

Bean, L. C., Acting Assistant Surgeon. Granted leave of absence for two days.

Appointment.

McIsaac, Frederick C. Appointed Acting Assistant Surgeon, United States Marine-Hospital Service, for duty at Evansville, Indiana.

Resignation.

Brunner, W. F., Sanitary Inspector. Resignation accepted as tendered, to take effect June 30, 1899.

**Births, Marriages, and Deaths.**

**Born.**

Reynolds.—In Ellenburg, New York, on Saturday, July 8th, to Dr. and Mrs. H. H. Reynolds, a daughter.

**Married.**

Brown—Merrill.—In Everett, Massachusetts, on Monday, July 10th, Dr. Roscoe Ellsworth Brown and Miss Harriet Sophia Merrill.

Cooper—Sprague.—In Jersey City, on Wednesday, July 5th, Mr. Charles P. Cooper and Miss Olive A. Sprague, daughter of Dr. Seth B. Sprague.

Kingman—Cheever.—In Portsmouth, New Hampshire, on Thursday, July 6th, Dr. James H. Kingman, of Pawtucket, Rhode Island, and Miss Mary T. Cheever.

McPhee—Wells.—In New York, on Saturday, June 24th, Dr. John Joseph McPhee and Miss Louise Z. Wells.

Richardson—Toledano.—In New Orleans, on Saturday, July 8th, Dr. Farrar Richardson, United States Marine-Hospital Service, and Miss Corinne Toledano.

Slocum—O'Brien.—In Long Branch, New Jersey, on Thursday, June 29th, Dr. William H. Slocum and Miss Annetta O'Brien.

Tillinghast—Forbes.—In Providence, Rhode Island, on Wednesday, June 28th, Dr. Frank A. Tillinghast and Miss Anna M. Forbes.

**Died.**

Brown.—In Weedsport, New York, on Friday, June 23d, Dr. Ira D. Brown, in the sixty-eighth year of his age.

Clenedin.—In Santiago de Cuba, on Wednesday, July 5th, Dr. Paul Clendenin, United States Army.

Edwards.—In Charleston, South Carolina, on Tuesday, July 4th, Dr. John J. Edwards, in the forty-second year of his age.

Lyon.—In New York, on Sunday, July 9th, Louise Lyon, wife of Dr. Samuel K. Lyon.

McKenzie.—In Tatum, South Carolina, on Thursday, June 29th, Mrs. J. C. McKenzie, wife of Dr. John C. McKenzie.

Neilson.—In New Rochelle, New York, on Thursday, July 6th, Dr. William H. Neilson.

Wright.—In Orange, Massachusetts, on Saturday, June 24th, Dr. Walter M. Wright, in the fifty-third year of his age.

**THE LAW IN ITS RELATIONS TO PHYSICIANS.**

*By Arthur N. Taylor, LL. B.*

**XXVII. CIVIL MALPRACTICE, INCLUDING GENERAL LIABILITY OF PHYSICIAN TO PATIENT.**

(Continued from page 62.)

**Best Judgment Required.**—It will be remembered that the general standard of professional requirements is that the physician must possess a reasonable degree of knowledge, skill, and experience; second, that he must exercise ordinary care and diligence; and third, that he will use his best judgment in all cases of doubt. Having scrutinized the first two requirements of this standard, attention will now be particularly given to the third.

It may be considered an axiom, de facto as well as legal, that one can not use good judgment in the treatment of a case without first possessing the adequate amount of knowledge and skill and exercising the proper degree of care. Dr. McClelland,* in his collection of malpractice cases, cites the case of Courtney v. Henderson, decided in the marine court of New York, in which a man, fifty-seven years of age, who had been under the care of an eye infirmary for eight weeks, was induced to withdraw from that institution and put himself under the defendant's treatment. While in the infirmary there was a gradual improvement of his eyes, but soon after placing himself under the care of the defendant the improvement ceased, the disease became more aggravated, and the eyesight gradually failed. The defendant treated the eyes about three months, and during this time performed an operation upon them and put some kind of powder into them. At the end of the three months treatment the plaintiff returned to the eye infirmary, but his vision was gone, never to return. The only expert evidence offered was that of two physicians from the infirmary, who testified that they had no doubt the plaintiff would have recovered under proper treatment. They also testified to their mode of treatment in such cases, which differed materially from that of the defendant. It seems that no expert evidence was offered showing that the defendant's treatment was either skillful or proper, nor any evidence to show that he was a qualified physician and surgeon. The defendant's counsel urged that the failure of the defendant to properly treat the plaintiff was the result of an error in judgment, and for that he was not liable. The court held that this was a good defense when applied to one skilled in the science of medicine, but that the defend-

---

* McClelland on Civil Malpractice, p. 273.
ant, knowing nothing of anatomy, surgery, or physics, was incapable of having judgment in the matter. The court accordingly affirmed the judgment rendered in favor of the plaintiff and against the defendant for malpractice.

The law, it has been observed, requires only that the knowledge possessed and the care and skill exercised shall be "ordinary" or "usual," but the judgment must be the physician's best judgment. What is one's best judgment is, from the nature of the case, absolutely impossible to determine, the judgment of no two men being the same in all respects. Because of the uncertainty of a rule of liability based upon the judgment of the party whose actions were the subject of litigation, an English court refused to entertain the plea that an error of judgment was a defense. Justice Tindal, in that case, said: "Instead, therefore, of saying that the liability for negligence should be controllable with the judgment of each individual, which would be as varied as the length of the foot of each individual, we ought rather to adhere to the rule which requires in all cases a regard to caution such as a man of ordinary prudence would observe." The justice did not, at the time of uttering these words, have in mind the judgment of a professional man exercised in performing the functions of his profession, yet the principle will apply, for the exercise of judgment must be such as not only to preclude the idea of professional incompetency and of a want of reasonable care, but the judgment itself must be consistent with the use of that degree of skill that it is the duty of every surgeon to bring to the treatment of a case, according to the standard of skill and care indicated.† For this reason nothing short of one's best judgment will be adequate.

A physician who possesses the requisite amount of knowledge and skill, and exercises his best judgment in determining upon such treatment as experience has shown him to be best, is not liable in damages from an injury resulting from an error of judgment.‡ Such judgment, in order to be a complete protection to the physician, must, however, have been exercised in a case where competent physicians might honestly doubt as to the nature of the disease or the proper method of treating it. In such a case all that the law requires is that a physician shall summon to his assistance all of his knowledge and skill, and in the light of their aid exercise his best judgment. If, however, the case is such a one that no physician possessing ordinary knowledge and skill would doubt or hesitate, and but one course of treatment would be suggested by a competent professional man, then any other course of treatment might be evidence of a want of ordinary knowledge or skill, or proper care or attention. In determining whether or not a physician may safely exercise his judgment in a given case he should first consider his general qualifications as a practitioner of medicine and his competency to handle the particular case; for if he is competent to treat the case, but is in doubt as to the nature and extent of the injury or the proper mode of treatment, he is justified, and it is his duty, to use his best judgment in deciding upon the nature of the disease or injury and fixing upon a course of treatment, and also as to whether or not he will consult with some other physician and surgeon. But if, on the other hand, he is not competent to treat the case, or feels that he is not competent, he should recommend the patient to some other physician.⑨

Theoretically, it is not difficult to lay down a rule which commends itself both to our reason and our sense of justice, defining those errors of judgment from which no cause of action should arise. Such a rule is the one laid down by Justice Richmond, which is that "Physicians are not responsible for the errors of an enlightened judgment, where good judgments may differ; and I can come to no other conclusion than that, when there are reasonable grounds for doubt and difference of opinion, the professional man, after the exercise of his best judgment, admitting that he possesses the necessary knowledge, is not responsible for errors of judgment or mistakes, and is only chargeable with errors which could not have arisen except for the want of or the exercise of reasonable skill and diligence." But is it in the practical application of such a rule that the difficulty lies. What things must the physician know as a matter of knowledge and what may he assume through the exercise of his best judgment? In the case of Du Bois vs. Decker † the plaintiff had a portion of his foot crushed beneath the wheels of a locomotive. The physician, hoping to save the foot, deferred amputation for nine days; then, seeing that the foot could not be saved, amputated the leg just above the ankle. Shortly afterward gangrene appeared, rendering further operation necessary. At the trial evidence was given tending to show that the bones of the foot were so crushed that immediate amputation of the injured portion was necessary, and that the appearance of gangrene was in consequence of the delay in operating. The counsel for the defendant claimed that the defendant, in the exercise of his best judgment, believed the foot might be saved, and that he could not be held liable for an error of judgment. But the court failed to agree with the defendant's counsel; it said: "But his judgment must be founded upon his intelligence. He engages to bring to the treatment of the patient care, skill, and knowledge, and he should have known the probable consequences that would follow from the crushing of the bones and tissues of the foot." On the other hand, if the injury sustained in such a case were not so serious as to preclude the probability of the recovery of the injured member, and the defendant were to produce competent and skilled physicians at the trial to testify that a recovery might be reasonably expected, and that the course of treatment adopted by the defendant was proper or best calculated to effect a recovery, then no reason can be seen why the defendant should not have been released from all liability.

A physician in the exercise of his judgment is not bound to anticipate or foresee any unusual or improbable result of his treatment. In the case of Bogle vs. Winslow, the plaintiff, who had a few days previously received a severe blow on the head, called upon the defendant, a dentist, for the purpose of having some teeth extracted. The defendant administered chloroform and took out the teeth. A few hours afterward the plaintiff complained of numbness of one side, which in a few days was followed by a stroke of paralysis. The plaintiff brought suit against the dentist, claiming that the paralysis was the direct result of the chloroform. Con-

siderable expert evidence was given, most of it to the
effect that paralysis could not result from the use of
chloroform. Some testified that it might result from
the use of such an anesthetic. There was also evidence
that the severe blow on the head received by the plain-
tiff might have produced a latent disease only requiring
some exciting cause to make it into activity.

The judge was of the opinion that if the administer-
ing of the chloroform or the extraction of the teeth was
the cause of plaintiff’s paralysis, still it would not be
just to make the defendant answer in damages for con-
sequences which he could not foresee, and which were
not the ordinary or probable result of what he did. The
jury was so instructed and found a verdict for the de-
fendant.

The rule that a physician is bound to exercise his
best judgment being one of universal application, it
necessarily follows that when he is called upon by a
patient to perform an operation which in his judgment
is unwise or unnecessary, he is bound to advise against
such operation whether his opinion is asked or not. In
the case of Gramm vs. Boener* the defendant had set
the plaintiff’s arm. Several weeks after, the bones ap-
ppeared slightly out of place, either from having become
untamed or from not having been originally accurately
adjusted. The plaintiff asked the defendant to rebreak
and readjust the bones, but the defendant advised
against the operation. He told the plaintiff that to re-
break the bones would be of no use; that it had better
be left alone, and that he ought not to think of it. But
upon the plaintiff’s insistence, he finally performed the
operation. The result was so unsatisfactory that suit
was brought. In the supreme court, upon the appeal of
the case, the question arose whether the defendant was
justified in finally deferring to the judgment of the pa-
ient and breaking the arm, or whether he should have
refused to operate altogether when such an operation
was contrary to his own best judgment. The supreme
court was of the opinion that the defendant had in-
curred no liability under the circumstances in operating.
Upon this question Justice Worden said: “But if a sur-
geon, when thus called, advises a patient who is of ma-
ture years and of sound mind that the operation is un-
necessary and improper—in short, advises against the
performance—and the patient still insists upon the per-
formance of the operation, in compliance with which
the surgeon performs it, we do not see upon what prin-
ciple the surgeon can be held responsible to the patient
for damages, on the ground that the operation was im-
proper and injurious. In such cases the patient relies
upon his own judgment, and not upon that of the sur-
geon, as to the propriety of the operation; and he can
not complain of an operation performed at his own
instance and upon his own judgment, and not upon that
of the surgeon.”

If in the physician’s best judgment it is advisable to
withhold from a patient in a particular emergency a
knowledge of the danger and extent of his disease, he
will be justified in so doing. So, when a physician, in
attending a patient who was suffering from a felon, told
her that her hand was doing well, and that she ought to
be thankful that it was so well, he was held to have in-
curred no liability thereby, it not appearing that the
patient desired to secure counsel, or was deterred by the
physician’s statement from so doing.†

Nor is there any legal necessity that the physician
should acquaint the patient with the character of the
operation or treatment he proposes to employ.* The
advisability of such a step is purely a matter of judg-
ment, and in such matters the exercise of the physician’s
best judgment is all that the law requires.

(To be continued.)

Pith of Current Literature.

An Internal Plate for Ununited Bones.—Potarca
(Presse médicale, April 19; Medical News, July 1st)
cuts down upon an ununited fractured bone, squares
the two ends, and holds them in a correct position,
closely approximated, by a thin metal plate which is
screwed fast to each fractured end, just as one might
mend a broken cane. The after-treatment is very sim-
ple. Held together so accurately, the bones quickly
unite, and when union is sufficiently solid, the plate is
exposed by a new operation, the screws taken out, the
plate removed, and the new wound allowed to heal.
There are no complications to be feared if the plates
are capable of being sterilized and are made of some
metal which will not decompose or form poisonous salts
in the fluids of the human body. Nickel, almost pure,
answers these requirements better than silver, platinum,
aluminum, or copper. This method of treatment is also
recommended in recent fractures in which reduction
cannot be obtained or can not be maintained. Thanks
to the X ray, the relations of the ends of the bone can
be determined with exactness, and an immediate opéra-
tion be performed if it is found to be desirable.

The Parasite of Cancer.—Dr. William Russell
(Scottish Medical and Surgical Journal, May) says
that increasing clinical and pathological experience
only deepens his conviction of the infectivity of can-
er. He is fully aware that many minds are ranged on
the other side, including some of his personal friends;
but he concedes himself by remembering that it took
some of his friends almost a decade to accept the Bacillus
luberosus as the aetiological factor in tubercle. The
author’s present purpose is confined to the question of
the infective element.

Up to 1890, Albarran, Dairer, Thoma, Wickham, and
Sjöbring had described structures in the cells of can-
er which they believed to be parasitic, and all of them
with the exception of Thoma regarded the parasite as
belonging to the protozoa.

Dr. Russell in 1890 described what he believed to be
a parasitic organism in cancer. The organism was
described both in an extracellular and an intracellular
form. They were held by him to be blastomyocytes, and
he provisionally called them “fuchsin bodies.” The
subject was taken up with considerable ardor, and it
was found that bodies similar in appearance to the
extracellular forms described occurred in morbid con-
ditions other than cancer. Some of the observations by
others were correct, some were wrong, as sufficient allow-
ance was not always made for the care with which the
author had excluded the possibility of the extracellular
forms being some of the things they were said to be.
Still the fact remained that identical bodies were found

* Gramm vs. Boener, 56 Ind., 495.
† Twombly vs. Leach, 65 Mass., 597.
* Boydston vs. Göntner, 3 Ore., 118.
in other morbid conditions, and this fact became a stumbling-block. After this, other work appeared which dealt with the intracellular structures in cancer cells, and in which it was attempted to differentiate the intracellular appearances into organisms, degenerations of cell protoplasm, or degenerations of cell inclusions not parasitic. The organism was regarded by these observers as a sporozoan, or at all events an ameboid parasite. A considerable array of observers, including Bergonzini, Klein, Raun, Hauser, Shattuck and Ballance, Goldmann, Rossi, Touton, Mantegazza, Pelagatti, etc., contended that the appearances described were the result of degeneration of one kind or another, or of something else. The variety of explanation has been great, and it is not going too far to say that the effect was that the current view has been that all work contending for the parasitic nature of the appearances was either wrong or wrongly interpreted. When Ruffer brought forward his work at the annual meeting of the British Medical Association Dr. Russell stated that his preparations were so beautiful that it was vain to continue the subject from the morphological standpoint, as nothing more could be made of it; that the two opinions would continue to be held—namely (1) that they were parasites, and (2) that they were merely degenerations. Experimental work by those whose circumstances permitted them to pursue the subject could alone settle who was right.

Within the past few years experimental work has been, in the author's opinion, gradually determining this question. To investigators in Italy we are indebted for its elucidation.

The honor and the credit of the experimental work belongs, in the first place, to Professor Francesco Sanfelice, director of the institute of hygiene in the Royal University, Cagliari. Before entering on an account of his work, it is necessary to state that when the author published his paper the dictum of pathologists was that the blastomyces were not pathogenic, and this authoritative dictum ruled men's minds as dicta of the kind usually do.

Sanfelice's Discovery of a Pathogenic Blastomyces.—Sanfelice was engaged in investigating the morphological and biological characters of blastomyces when he found that one of these was pathogenic, and was interesting not from this fact alone, but from the further fact of its morphological resemblances to the bodies which had been described as cancer coccidia. He then, apparently, looked more fully into the literature of pathogenic blastomyces, and from this it appeared that Neumayer and Raun had both experimentally inoculated animals with pure cultures, but without results of importance. Busse had described a case diagnosed as sarcoma of the tibia, in which numerous cells were found, which Loeffler cultivated and pronounced to be blastomyces. Experimental inoculation with these only proved that the parasite was capable of reproduction in the animal body. Maffucci and Sirleò described a blastomyces obtained from a guinea-pig with which they were able to inoculate other guinea-pigs.

This seems to have been the position as regards pathogenic blastomyces, when Sanfelice began the investigations to which special reference is to be made.

The special organism with which Sanfelice experimented he has called the Saccharomyces neoformans. Inoculation of guinea-pigs with it showed that wherever inoculation was performed the result was a general infection of the animal with the formation of tumors, consisting partly of masses of the parasite and partly of proliferation of the cells of the part. The infection spread by the lymph and blood channels and did not cause inflammation. The animals usually died within a month; and Sanfelice noted that in the tissues the parasite had a somewhat different appearance to what it had in cultures. The appearances of this parasite in the tissues of guinea-pigs had a great resemblance to the bodies found in human malignant growths by many observers. Most of these authors believed these bodies to be coccidia, and it was by Russell alone that the bodies were believed to be blastomyces. In mice, inoculation led to a rapid infection with great multiplication of the parasite. In white rats the process was slower, the animals dying after a month and a half to two months, and with more reaction on the part of the tissues. In rabbits, only two out of twelve inoculated died, and in the fatal cases the parasites were fewer in number, but there was more proliferation of the tissue elements than in the other animals. Out of thirty dogs inoculated, only two developed a tumor at the point of inoculation and metastasis in internal organs. One of these dogs was killed after four months, the other died after ten months. The pathological changes in the first dog consisted in the development of a nodular tumor in the mammary gland where the inoculation had been made, with enlargement of neighboring lymph glands. The changes were like those of a sarcoma. Very few parasites were found, and no cultures could be obtained from any of the tissues. In the second dog the growths were different, but Dr. Russell has so far failed to find an account of the anatomical changes present in it. In fowls the parasite presented a different appearance to the appearance in the other animals.

The Morphological Characters presented by the Blastomyces when Inoculated into Animals.—In a paper dated September, 1897, on the Experimental Production of Russell's Fuchsian Bodies, Sanfelice says that until that time among the animals he had inoculated with Saccharomyces neoformans it was only in dogs that the blastomyces appeared in the typical forms as described by Russell under the name of "fuchsian bodies." Russell described them as certain structures which he could almost always demonstrate in carcinomatous. They were almost spherical, four to twelve millimetres in diameter, homogeneous, and without a trace of structure. They lay almost always in groups of three to twenty elements; some of them were bounded by a thin rim of cell protoplasm, while the majority lay in a clear area in a kind of vacuole. They were met with either in the cancer cells or in the stroma. Russell believed these to be parasites, and classed them under the blastomyces or sprouting fungi.

Sanfelice goes on to say that since the previous year he has been inoculating various animals with pure cultures of the Saccharomyces neoformans, and had noted that in certain cats which died after some months the blastomyces inside the tissues took the typical forms of Russell's bodies; and in view of the appearance of the works of investigators who denied that Russell's bodies were blastomyces he proceeds to report on the manner in which the parasites appear in these particular animals.

When he ascertained that after injection of pure cultures of Saccharomyces neoformans in cats, typical Russell's bodies appeared in the tissues, he investigated the tissues of normal cats, but in no case found Rus-
sell's bodies. After inoculation with Saccharomyces neo-
formans, the fuchsian bodies were invariably found, and,
moreover, presenting the same form and arrangement, and
with the same reaction to coloring material, as the
bodies which Russell and others had described as occur-
ing in malignant tumors.

In the inoculated cats the fuchsian bodies appeared in
the greatest number in the lymph glands of the mesen-
tery, in the spleen, and in the bone marrow. They were
easily recognized, being perfectly round in form, and in
depth varying from that of a microcos to that of a
leucocyte. As regards structure, some of the bodies
showed a differentiation of the chromatic substance,
while others took on the stain homogeneously, with
more or less intensity. The bodies with differentiated
chromatic substance possessed either a kind of circle
or an intensely colored membrane with a less intensely
colored central part, or they showed a deeply colored
core surrounded by a circle only faintly colored, or
not colored at all, and varying in breadth. The homo-
genously colored forms took on a more or less deep
color.

In many of the parasites multiplication by budding
might be seen, in the same way as is seen in artificial
cultures. The buds grew from the smaller elements
as well as from the larger, and might or might not
remain attached until they attained the full size.

In the tissues of cats the blastomyces were found,
either lying free or inside the cells. The free forms
lay between newly formed cell elements, and usually in
groups, seldom singly. The number of parasites in one
figures varied. Sanfelice has counted as many as thirty
in one group. Sometimes these were so closely clus-
tered as to present a mulberry appearance; sometimes
they lay separated from each other, and, moreover, at
such equal distances that it seemed as if some cement
substance kept them at equal distances and prevented
direct contact of the deeply colored substances.
Occasionally one could see quite distinctly that this apparent
cement substance was formed from the circles or hya-
line membranes, which by touching each other con-
sealed the outlines of their peripheries. In some groups
of blastomyces the hyaline membranes were very ap-
parent, and their borders were distinctly seen.

The endocellular parasites were usually much
smaller than the free forms. The number of inclosed
parasites varied as did the free forms, and they pre-
sented the same appearances. According to the posi-
tion in which the cell containing the parasites was seen
by the observer, the nucleus appeared either pushed to
one side, or in the centre of the cell, surrounded by
parasites. Small parasites in considerable numbers
were often found lying close together in a ground sub-
stance, without any nucleus visible. Perhaps in these
cases the nucleus lay under the parasites, so that the
eye of the observer could not detect it. Another feature
was the fact that they were found in the neighborhood
of young, newly formed cells, and did not appear in the
parts where the cells were undergoing degeneration.
Sanfelice concludes by stating that this communication
is intended to prove: 1. That all authors who contend
that Russell's fuchsian bodies are not blastomyces have
not hitherto brought forward experimental proof
that they are cellular degenerations. 2. That through
the inoculation of cats with pure cultures of Saccharo-
myces neoformans the typical bodies are produced
which have been described by Russell and others as oc-
curring in malignant tumors in man, and in certain
chronic inflammatory processes. 3. That these fuchs-

Sanfelice states that the pathogenic blastomyces hitherto cultivated closely resemble another on
artificial media and in morphological appearances,
while at the same time their pathogenic action varies
widely.

The Experimental Production of Epithelial Tumors
and Metastatic Epithelial Growths.—The next still
more interesting point was to ascertain whether the in-
jection of these blastomyces into animals susceptible
to malignant tumors would bring about the formation
of neoplasms similar to the malignant tumors observed
in man. Sanfelice approached the solution of this prob-
lem by passing the blastomyces with which he was ex-
perimenting through a number of dogs—that is, from
dog to dog. By this method he arrived at positive
results in two cases. In one of these the dog had been
inoculated in the two posterior nipples, with the blasto-
myces which had been passed through several dogs.
After a slight inflammatory reaction at the site of in-
oculation the nipples remained apparently normal until
about a month after the operation, when signs of a neo-
plastic process became evident. The animal died ten
months later, with marked cachexia, tumors in both
tests, showing retraction of the nipples and tucking
down of the skin, and secondary growths in the inguinal
and abdominal lymphatic glands. All these showed the
typical structure of adenocarcinoma. Sanfelice's col-
leagues Biondi and Carboni confirmed this opinion. No
parasites were observed in the centre of the primary
tumors. A few were observed in the peripheral part
of the primary tumor, and in the metastases in the
glands. Sanfelice could obtain no cultures from any
of these growths: the explanation he offers of this is
that when the parasite has so grown accustomed to its
surroundings as to take on the typical characteristics
of Russell's bodies, and to become capable of producing
malignant tumors, from that time it becomes incapable
of growing in artificial media, meaning this the
ordinary media on which he had grown his Saccharo-
myces neoformans. In order to be grown artificially
the parasite must occur in the form in which it occurs
in guinea-pigs, etc.—that is, in the form usually found
in infections running a rapid course, and seldom in
those running a more prolonged course. If blastomy-

cetes are isolated from malignant growths of man or
animals Sanfelice holds that they must have been pres-
ent in the growth in both forms.

Further inoculation experiments were given, but
these need not be given in detail. It is sufficient to
state that a few positive results were obtained by in-
oculating dogs from the new growth in one of the cases
referred to above.

Inoculation into the Circulation and Abdominal
Cavity of Dogs and Cats.—Inoculation of dogs in the
jugular vein led in the course of from one month to
a month and a half to connective-tissue changes in
which the parasite was present in small numbers and in
its cultivable form. In the case of cats, Sanfelice found
that the Saccharomyces neoformans inoculated into the
abdominal cavity or veins brought about the same
changes as he had observed in the bodies of dogs inocu-
lated in the same way. In the case of cats, he con-
firmed his opinion that when the parasites had been long enough in the body to assume the typical forms of Russell's fuchsin bodies they were no longer cultivable in artificial media. If, however, the cats were killed soon after inoculation, cultures could be obtained, the parasite then presenting the forms which occurred in guinea-pigs and rabbits where the infection ran a more acute course. One of the conclusions Sanfelice draws from his experimental work with the Saccharomyces neoformans is that it appears in the tissues of animals in two forms. In one form it possesses a capsule and is cultivable in artificial media. In the other it has no capsule, is identical with the fuchsin bodies of Russell, and can not be cultivated in artificial media. This second form is only observed in the organism when the parasite has lived in it for some time.

Roncali's Histological Contribution.—Professor Roncali, of Rome, has taken a leading part in the appreciation of Sanfelice's work and has published important papers on the histological appearances in some malignant tumors in man. He was attracted by the fact that in a case of adenocarcinoma of the ovary there were appearances identical with those described by Sanfelice, and he came to the conclusion that they were due to the same cause, the presence of a parasitic blastomyces. He also noted the resemblance between the appearances in his case and those described in cancer and regarded by some authors as parasitic. He acknowledges, with scientific justice and frank generosity, that all authors had seen real parasites, but they had erred in assigning them a place in the animal kingdom, being led, he thinks, by a false prejudice, wishing to see sporozoon, which circumstance had proved the inexhaustible source of all the errors made. He records three cases, two of adenocarcinoma of the ovary and one of adenocarcinoma of the colon with secondary involvement of the great omentum and mesentery. In all he found the same appearances, and he has no doubt as to their nature. He describes and figures the parasite both as extracellular and intracellular. From one of his cases he obtained cultures of blastomyces. Inoculation of guinea-pigs with these cultures caused death of the animal, and the production in many of the organs of little whitish nodules. These were of the nature of granulomata, only with more of the characteristics of new growth than of inflammatory products. The nodules showed many parasites, young and degenerated, and Roncali found them to be identical with a blastomyces isolated by him from an epithelioma of the tongue. Roncali records a large series of experiments to prove that the parasites had not reached the tissues from the air after removal from the body. He showed by these that dead tissue, whether of normal organs or of tumors, was not suitable for promoting the growth of blastomyces, and that blastomyces showed no preference for the tissue of malignant growths. Roncali next discusses the question of the etiological factor in human neoplasms, and concludes that the genetic connection between the blastomyces and malignant tumors is proved.

Work of Other Observers.—Busse cultivated a blastomyces from a sarcoma, as has been already referred to. Kahane got pure cultures of a blastomyces from a cancer of the uterus. Mafucci and Sirlea have discussed the blastomyces as the cause of malignant tumors, but their results are mainly negative, while not denying the possibility of a connection. An important case has been recorded by Corselli and Frisco of sarcoma of the mesenteric glands, from which they were able to isolate blastomyces which produced similar growths in guinea-pigs, rabbits, and dogs. They got pure cultures of blastomyces in the patient's lifetime, and after death from fluid from the abdominal and thoracic cavities. Curtis had a case, referred to by Sanfelice and Roncali, of a myxomatous tumor in a man, from which he obtained cultures of blastomyces, and by inoculation produced a tumor in a rabbit.

Conclusions.—Dr. Russell concludes by saying that to any one going carefully through Sanfelice's work there is only one opinion possible, and that is that it is a very careful and beautiful piece of investigation and research. The links in the chain of evidence are simple and strong, and may be thus summarized: Investigating blastomyces, he finds appearances similar to those described as occurring in cancer both inside and outside the cells. Working on these lines, he familiarizes himself with the appearances presented by the parasite in the tissues and organs of different animals. He finds that in different animals the pathogenic effect varies from a somewhat rapid infection with great proliferation of the parasite down to a much less acute infection. In dogs, by inoculating them into the peritoneal cavity, he recovers the parasite from the lymph glands and passes them through another dog, and so on. Having in this way modified the parasite by the chemical-vital influences in the dog's body, he inoculates the mammas and the testicles of dogs with the modified organism, and finds that it produces epithelial growths with metastases.

The success of others in cultivating blastomyces from tumors, mainly malignant, adds confirmation to Sanfelice's results. Roncali is one of these, but his confirmation is largely from the histological standpoint, and he was avowedly greatly aided in his observations by his acquaintance with the appearances in the tissues produced by inoculation with the Saccharomyces neoformans as followed by Sanfelice.

The Influenza Bacillus and Pneumonia.—Dr. W. H. Smith (Journal of the Boston Society of Medical Sciences, May), as the result of researches in the clinical pathological laboratory of the Massachusetts General Hospital, arrives at the following conclusions: 1. Cases of pneumonia caused by the influenza bacillus may give few, if any, signs clinically of their presence beyond a moderate degree of fever and a few fine, moist rales, more or less circumscribed. 2. The influenza bacillus by itself is capable of producing pneumonia; however, the pneumococcus is frequently associated with the influenza bacillus in its production. 3. The type of the pneumonia is usually broncho or lobular, frequently consisting of multiple foci, with a tendency to involvement of the lower lobe of the left lung. 4. Upon microscopic examination the exudate is composed largely of cells, chiefly of leucocytes. The amount of fibrin present in the exudate is small. Bacilli usually are present in large numbers inside of the leucocytes, both in the alveolar spaces and in the bronchi.

Delivery of the Arms when Displaced Upward in Breech Cases.—Dr. T. M. Callender (British Medical Journal, June 10th) recently attended a case of labor with pelvic contraction, the child presenting transversely. Turning was resorted to and the legs brought down. The uterus was carefully followed with the hand in its descent, and as the pulsations of the cord were only imperceptibly felt traction was made on the legs in the
axis of the parturient canals. The arms, however, became displaced upward and could not be brought down by the usual digital method. He therefore knotted a corner of a soft handkerchief and passed it round the shoulder which lay anteriorly, it being most accessible. Then, having pushed the handkerchief along the arm to the elbow, it was kept there by a finger of the left hand while with the other hand he exerted traction on the handkerchief in a direction obliquely across the anterior aspect of the child's body. In this way he managed to pull down the arm without difficulty. The other arm was then easily brought down with the fingers. Dr. Callender considers the method freer from danger than the use of a blunt hook. The danger of causing fracture of the shaft of the humerus or dislocation of the head of that bone is to be avoided by, 1, keeping the handkerchief at the elbow by means of the finger, and, 2, by pulling in a direction obliquely across the anterior surface of the child's body. The "lacue," he says, has been mentioned by authorities as useful sometimes in bringing down a breech, but he has not noticed anything of the kind mentioned as of use in bringing down the arms, hence his reason for publishing the case.

Carbolic Acid as a Test for Albumin.—Dr. Walter Colquhoun (Lancet, May 6th) recommends a saturated solution (approximately six in one) of carbolic acid in absolute alcohol as a test equaling in delicacy the nitric-acid test, and as giving perfect satisfaction after a short experience in working with it. Dr. Colquhoun's procedure is as follows: The test solution having been made by dissolving carbolic acid to saturation in absolute alcohol, the author floats a few drops of the solution on the top of the fluid to be tested by means of a pipette. Owing to the greater solubility of carbolic acid in alcohol than in water, the layer of testing fluid on the surface becomes opaque and rather milky looking from the separation of carbolic acid, as water is imbibed in the transfer between the urine and the alcohol. As the alcoholic solution of carbolic acid imbibes more water and becomes heavier, drops also of a milky appearance on their surfaces may detach themselves and fall to the bottom of the test tube. If much albumin is present the whole of the fluid to be tested may become milky, and the alcoholic layer may settle quickly to the bottom of the test tube with large milk-white flakes of albumin attached to it. In the case, however, of the presence of only a small quantity of albumin, the test tube must be allowed to lie for some time just as in the nitric-acid test, and the presence of albumin will be denoted by a milkniness extending to a certain depth below the alcoholic layer. As has already been remarked, milky looking drops of the alcoholic solution of carbolic acid may separate and fall to the bottom of the test tube. This happens even when the alcoholic test solution is floated on top of pure water and, as has been explained, the milkniness is due to the imbibition of water and consequent separation of carbolic acid. That this milkniness is not necessarily due to albumin may be shown, when only a trace of that substance is present, by passing the bottom of the test tube two or three times through the flame of a spirit lamp, when, carbolic acid being more soluble in warm water than in cold, the milky deposit at once clears up. The milkniness at the upper part of the test tube below the alcoholic layer is, however, due to coagulated albumin, and does not appear unless that substance is present, nor is it dissipated by heat.

As regards the fallacies of the test, the author has

as yet found none which were not attributable to careless manipulation. Mucin may be precipitated by alcohol, but he has had no trouble owing to its precipitation yet. He clears the urine, preferably by filtering, and it may be remarked in this connection that the best Swedish filtering paper, such as is used for quantitative work, clears urine which a cheaper paper would allow to pass through cloudy. Another point worthy of mention is that cooling for a few moments, as, for example, by playing an ether spray on the upper part of the outside of the containing vessel, will often bring down a cloud of urates before filtering and is besides instructive as regards the degree of saturation of the fluid. In both the nitric-acid and the carbolic-acid tests the urine should be diluted to about specific gravity, 1.010. The proved delicacy of these tests allows plenty of margin for dilution, and if after dilution no albumin is found, its presence is in the author's opinion negligible. Indeed, he has found albumin present in small quantities in the urine of such a large proportion of his patients that he is coming to regard its presence merely as a warning to make a careful examination and a guarded diagnosis. If the urine were always diluted before applying the nitric-acid test the fallacies of that test would probably disappear. In the case of the carbolic-acid test it is important that the fluid tested should not have too high a specific gravity, since in that case the interchange between the alcoholic layer and the fluid tested is too slow. The dilution may be continued to a specific gravity below 1.010 without greatly affecting the result, if such a course is wished. The author says that since he began his investigations he can speak with certainty as to the presence or absence of albumin, whereas before he had undertaken them he would not have liked to certify in certain cases.

Book Notices.

The work before us is a most exhaustive study of pulmonary diseases, and, representing as it does the most advanced thought upon the various disorders it treats of and prepared by two observers whose experience has specially entitled them to speak, it is a production of great value.

The arrangement of the volume is not unusual. It opens with a presentation of the anatomy of the parts; to this succeeds a chapter upon physical diagnosis, and then the various disorders of the trachea, bronchi, lungs, and pleura are considered. The character of the book throughout is of great excellence, as has already been said, but neither the form nor the material is of a character sufficiently different from that of several of the recent works upon thoracic disease to require comment in detail. The volume is handsomely prepared and well illustrated, the most serious fault being a type too small for easy reading.

It will, no doubt, be thought that our notice of this work is not commensurate with the importance of the book. This is certainly and undeniably a fact, but it is intentional on our part, since in the space at our command we can not pretend to do the volume justice, so far as criticism is concerned. Anything we might say, indeed, would performe to laudation, for the work is one of those scholarly productions that are all too rare in the medical field, and of an exhaustiveness and a completeness that make it classical. We are nothing less than enthusiastic as regards the book—possibly our readers will think us overenthusiastic, but scarcely, we believe, when they have read the book.

Not only in text is the volume unusual, the publishers’ work is beautiful, and never have we seen more excellent illustration in a medical book. The possession of a book like this is a great satisfaction.

The feature of this work that commends itself in particular to the practitioner is the stress it lays upon urinary microscopy. Chemical uranalysis, indeed, is not neglected, but the bulk of the volume is devoted to microscopic examination as a means of diagnosis. The concluding part of the book, which is devoted to this sort of diagnosis, is a model for clearness and for straightforward presentation. The text is enriched with many illustrations which have been prepared from drawings. Without exception they are clear and instructive. At first sight it is hard to imagine the claim that a new work upon urananalysis should have to our recognition, for in few branches of medicine are there so many excellent works already, but we must confess that in Dr. Heitzmann’s book we find much to admire and a good deal that the others do not contain.

This little volume presents with brevity and much force the well-known views of its author upon the subject of dietetics. In no respect is it a departure from what Dr. Haig has already told us, and in fact the frequent references it contains to a previous work by the same hand go far to deprive it of novelty and, in our opinion, are in bad taste. Those who are so fortunate as to be possessed of the author’s work on _Uric Acid as a Factor in the Causation of Disease_ will hardly require this recent addition to the uric-acid family, although in some respects, we think, the smaller is to be preferred to the larger work.

This work, by the careful compilation and lucid arrangement of its contents, should commend itself both to students and to practitioners. So much has been written on this subject, so many theories have been advanced, that one can not fail to appreciate a careful review of all that is tenable, and this is to be found in Dr. Nestor’s book.

**BOOKS, ETC., RECEIVED.**

A Selected Bibliography of the Anthropology and Ethnology of Europe. By William Z. Ripley, Ph. D., Assistant Professor of Sociology, Massachusetts Institute of Technology, etc. A Supplement to _The Races_

Transactions of the Southern Surgical and Gynecological Association. Volume XI. Eleventh Session, held in Memphis, Tennessee, December 6, 7, and 8, 1898.

Remedial Measures Proposed for Pennsylvania. By Samuel Wolfe, M. D. [Reprinted from the Transactions of the Twenty-fifth National Conference of Charities and Corrections.]

Gynecologic Diseases: Some Points in the Diagnosis of the more Common Ones. By T. J. Watkins, M. D., of Chicago. [Reprinted from the Journal of the American Medical Association.]

The Treatment of Endometritis. By T. J. Watkins, M. D. [Reprinted from the American Gynecological and Obstetrical Journal.]

Tampons and Pessaries in the Treatment of Displacement of the Uterus. By T. J. Watkins, M. D. [Reprinted from the American Gynecological and Obstetrical Journal.]

A Thorough Preliminary Education a Prerequisite of Success in the Practice of Medicine. By Anna M. Galbraith, M. D., of Philadelphia. [Reprinted from the Woman's Medical Journal.]

Appendicitis or Salpingitis with Complications, and a Report of some Unusual Cases. By Thomas H. Hawkins, M. D., of Denver. [Reprinted from the Medical Record.]

Septic Endometritis, with a Recovery after a Temperature of 113° F. By Samuel F. Brothers, M. D. [Reprinted from the American Medico-surgical Bulletin.]

Hypnotism and Suggestion, with a Case of Spasmotic Stricture of the Esophagus. By Samuel F. Brothers, M. D. [Reprinted from the Medical Record.]

Chronic Phthisis: A Case treated with Koch’s Improved Tuberculin, etc. By Samuel F. Brothers, M. D. [Reprinted from the Journal of the American Medical Association.]

Ein modifizierter “Cauterisator prostate” zur Bottini’schen Operation. Von Dr. Albert Freudenberg in Berlin. [Sonderabdruck aus der Berliner klinische Wochenschrift.]

Heilbarkeit des beginnenden grauen Staates. Von Dr. A. Klug, Freiheit-Johannisbad. [Sonderabdruck aus dem Aerzlichen Central-Anzeiger.]

New Inventions, etc.

A NEW METHOD OF INTESTINAL ANASTOMOSIS.

By J. W. Hartigan, M. D., MORGANTOWN, W. VA.

I send herewith a photograph of a section of a dog’s intestine, illustrating end-to-end anastomosis with the aid of light rings of large lumen. The rings used in this case were not specially made for intestinal work, but were of selenite, and of the sort used in the laboratory for making ring microscopic preparations. The question as to the kind of material to be used for making them can best be settled by experience. Bone, rubber, or aluminum would well answer the purpose.

They should be light and of large lumen. The facing surfaces may be made with eminences and depressions to prevent circular movements when in situ, or they may be left smooth. The surfaces facing the lumen and those opposite to those holding the peritoneal surfaces in contact, may, if absorbable rings are used, also be grooved. The grooves would hold the sutures when introduced, and so weaken the rings that they would break into small pieces. The length of time that they would hold would depend on the substance of which they were made and the depth of the grooves. In an article on Intestinal Anastomosis,
MISCELLANY.

107

The opinion, is due its popularity over the more difficult but more surgical and desirable method of Professor Mannsell—is still more marked in the operation with the rings. The lack of special skill required in any surgical procedure is, in my opinion, in favor of that procedure. The thing most to be desired in surgery is simplicity. When an operation completely and thoroughly meets the demands of a case, then the less technique required and the less skill demanded in its performance, the greater will be the number of surgeons who can do it, and the broader its range of usefulness. The ring operation can be done by any surgeon of ordinary care and training. With it there is less traumatism than with the Mannsell operation, and it can be done with much greater rapidity. The operation is done as follows: The piece of intestine to be removed is taken with its V-shaped section of mesentery, and the latter is united with interrupted sutures. Two sutures are passed from within out through the muscular and peritoneal coats of one end, and from without in through the peritoneal and muscular coats of the other end, and tied on the inside. This brings the peritoneal surfaces together at the mesenteric attachment. The rings are next introduced—one into each end of the divided gut—and pushed back a little beyond the free edge of the peritoneum. The sutures are then introduced by passing the needle from without in through all the coats of the gut behind the ring, through the lumen of the ring, and then from within out through the muscular and peritoneal coats about an eighth of an inch from the free edge of the cut intestine; then from without in through the peritoneal and muscular coats of the opposite end of the gut in front of the ring, through the lumen of the ring, and out through all the coats behind the ring. Several such sutures can be introduced before they are tied. When tied, the rings are drawn together and the peritoneal surfaces brought snugly into contact. Intermediate Lambert sutures can be used if necessary.

A Long-delayed Confined.—Dr. M. R. Adams, in the North Carolina Medical Journal for May 5th, records the case of a mulatto woman, aged forty-seven, the mother of five children, who ceased to menstruate during the winter of 1891-92. Enlargement of the abdomen and other symptoms led to the supposition of pregnancy, and in August, 1892, signs of labor set in, and continued for ten or twelve hours. The physician called in, after examination, was satisfied that the patient was not in active labor, but thought that it might be shortly expected. He heard nothing more till October 7th, when he was again summoned, as on the former occasion, to find all the prodromal symptoms, but no softening or dilatation of the cervix. A few weeks later a quasi-menstrual flow occurred and the patient recovered her health and went about her duties as usual. From this period she seemed all right until November 7, 1898, when fever and other symptoms pointed to sepsis. In January, 1899, Dr. Adams was summoned in consultation, and from the history laparotomy was decided upon. This was performed, and on opening the uterus the operator found and removed the osseous framework of a fully developed child, but entirely disarticulated and submerged in about a quart of green, gangrenous, offensive fluid. It would appear as though this child had attained maturity in August, 1892, and remained in the mother's womb until January, 1899—approximately six years and five months—without the mother having lost any of her time until nearly two months before the operation.

Christian Science Healers Committed.—According to the Buffalo Medical Journal for July, George H. Kinter and James C. Saunders were recently committed for trial before a United States jury on a charge of manslaughter in the case of Rolfe Saunders, who died while under their care without medical aid being sought.

Trial of Yellow-fever Serum.—According to the New York Herald for July 7th, Dr. Alvah H. Doty made the first trial of his yellow-fever serum in the human subject on a passenger from the United States transport McClellan on July 6th.

Vegetarianism and Religious Orders.—The Medical Age for June 25th says that it is publicly stated that there has been an important secession from the ranks of the vegetarians, the entire Dominican Order in England having received permission from Rome to eat flesh four days a week, instead of perpetually abstaining therefrom, as heretofore. In cases of ill health or of specially hard work, meat is to be allowed six days a week. This decision has been arrived at after the closest medical and official investigation of the effects of perpetual abstinence from meat in a variable climate like that of England, the result being that vegetarianism has been declared incompatible with physical strength and hard work.

Oyster Fever.—Dr. John W. Moore (Practitioner, March; Canadian Practitioner and Review, June) considers that oyster poison produces three distinct forms of febrile disease. The oyster toxaemia may act by causing a very acute illness. Within a few hours the person is suddenly seized with acute gastro-intestinal disturbance, as nausea, vomiting, and purging. After a few hours of misery the patient recovers rapidly. The second form is a continued fever. This fever is ushered in by chills, and lasts from a week to two weeks. There is much depression, and the case may end fatally by coma, convulsions, peritonitis, or heart failure. In some instances the acute form may be followed by this more chronic type. Where elimination in the acute cases is not complete, poisonous albuminoses are formed. These give rise to severe nerve symptoms, as paresis, heart failure, coma, etc. Then, thirdly, there is true typhoid fever, as has been so clearly pointed out by Dr. W. H. Broadbent.

Another Total Extirpation of the Stomach.—According to the Berne correspondent of the Medical News in its issue for July 1st, Dr. Kocher, of Berne, performed total extirpation of the stomach for carcinoma
Hermaphroditism and Marriage.—The Medical Age for June 25th says, with reference to a case we cited from the Archiv für Laryngologie, ix, 1, 1899, of a woman who had applied for laryngologic treatment, in whom Berthold noticed that the vocal cords had the appearance found only in the male adult, that the individual was a hermaphroditic, who eight years later returned for a certificate to allow the change of sex, having fallen in love with a woman.

The Late Dr. Francis E. Noble.—At a special meeting of the Committee on Necrology of the District Medical Society of the County of Hudson, held in Jersey City, July 1, 1899, to take action on the death of Francis E. Noble, M.D., the following resolutions were formulated and will be presented at the next meeting of the society:

Whereas, We have learned with deep regret of the death of that worthy man, eminent scholar, and humanitarian physician, Dr. Francis E. Noble; and

Whereas, The District Society of the County of Hudson feel with unalloyed sorrow the loss it will sustain in Dr. Noble's death;

Resolved, That we publicly express our appreciation of the man, our admiration for his character, and our individual loss in the death of Dr. Francis E. Noble; and

Resolved, That we tender our condolences to his family and friends, ever reminding them that as the brightness of Dr. Noble's intellect has been always a lamp unto our feet in times past, so shall his memory be as a luminous star beckoning us onward toward manliness, truth, and virtue; and

Resolved, That a copy of these resolutions be sent to the bereaved family of Dr. Noble and be printed in the New York Medical Journal, Medical Record, and the Evening Journal of Jersey City, and spread in full upon the minutes of the District Medical Society of the County of Hudson.

[Signed.] CHARLES K. LAW, M. D., President; H. H. BRINKERHOF, Jr., M. D., Treasurer; G. W. SHERA, M. D., Secretary.

The Chair of Physiology at Edinburgh University.—According to the Lancet for June 24th, E. A. Schäfer, M. R. C. S., LL. D. Aberdeen, F. R. S., Jodrell professor of physiology in University College, London, has been unanimously elected to fill the chair of physiology in the University of Edinburgh.

The Cremation of Lawson Tait.—According to the Lancet for June 24th, the remains of Mr. Lawson Tait were cremated at Anfield, Lancashire, and the ashes removed in an urn to be deposited, in accordance with his testamentary wishes, in Gogarth's Cave, an ancient Welsh burial ground at Llandudno, Wales.

The Italian Medical Society of the City of New York.—We are informed that on May 11th a medical society with the foregoing name was duly incorporated at Albany. The incorporators were Dr. D. A. Casella (New York University); Dr. A. Pisanl (College of Physicians and Surgeons); Dr. M. Luzzatto (University of Turin); Dr. J. Aquaro (College of Physicians and Surgeons); and Dr. G. B. Corsiglia (Long Island College Hospital).

The New Hampshire Medical Society held its one hundred and eighth anniversary meeting in Concord on May 25th and 26th. An unusually long programme was presented, nearly all of the papers being read and discussed, though a few were read by title and referred to the committee on publication. The attendance was large, and the meeting proved interesting to the members and delegates. The following officers were elected: President, Charles R. Walker, M. D., Concord; vice-president, William T. Smith, M. D., Hanover; treasurer, M. H. Felt, M. D., Hillsborough Bridge; secretary, Granville P. Conn, M. D., Concord. Executive committee: Dr. F. A. Stillings, Concord; Dr. George D. Towne, Manchester; Dr. William T. Smith, Hanover; Dr. F. E. Kittredge, Nashua; Dr. Ira J. Prouty, Keene; Dr. A. C. Heffenger, Portsmouth; Dr. G. W. McGregor, Littleton. Committee of arrangements: Dr. D. Edward Sullivan, Concord; Dr. Arthur K. Day, Concord; Dr. Frank W. Grafion, Concord; Dr. Sibley C. Morrill, Concord; Dr. George H. Parker, Concord. Anniversary chairman, M. S. Woodman, M. D., West Lebanon. The society has a council of twenty members and a board of censors, which includes the board of medical examiners and of registration for the State. The next annual meeting of the society will be held in Concord, May 31 and June 1, 1906.

Gastrotomy on a Horse.—The Tri-State Medical Journal and Practitioner for June records the fact that the first gastrotomy ever performed on a horse was recently done by a veterinary surgeon in East New York. The stomach was opened in order to effect the removal of a silver watch and some coins which had accidentally fallen from a stableman's pocket into the animal's manger, and were swallowed with its fodder. The operation was entirely successful, and it was recorded that the watch continued to go for an hour after being swallowed.

Conviction of a "Faith Healer."—We learn from the Journal of the American Medical Association for July 1st that the faith healer under whose treatment Dora Kraray, a child of Brooklyn, suffered from gangrene of the foot, making amputation necessary, has been sentenced to five years' imprisonment.

A Distinction without a Difference.—The St. Paul Medical Journal for July, in an editorial on The Passing of Homeopathy, says: "It is interesting to compare certain portions of the codes of ethics of the American Institute of Homeopathy and of the American Medical Association. In the former we find: 'Perfect freedom of opinion and practice is the unquestionable prerogative of the practitioner, who is the sole judge of what is the best mode of treatment in each case of sickness intrusted to his care. No greater misfortune can befall the medical profession than the action of an influential association establishing a creed or standard of orthodoxy.' In the code of the American Medical Association we may read: 'Neither is there any other article or clause of the said code of ethics that interferes with the most perfect liberty of individual opinion and practice.' Why, then," asks the St. Paul Medical Journal, "should honest practitioners ever call themselves homeopaths?"
Original Communications.

A STUDY OF DELIRIUM.

By WILLIAM HIRSCH, M.D.

From the earliest writers to the present day the word delirium has been used, in conformity with its etymology, as a collective term for the entire variety of mental disturbances. Every psychopathic symptom, of whatever character, arising in the course of disease, has been termed delirium. The habit has thus arisen of speaking of the most varied kinds of delirium, such as delirium of sensation, of judgment, of memory, of emotion. Even to-day we find any group of psychopathological symptoms described in the text-books and encyclopedias under the rubric delirium. Delusions, hallucinations, imperative ideas, etc., are spoken of as a delirium; and in French medical literature as well, délire d'emblée, délire d'énormité, délire de négation, délire du tacher, and the like, are frequently mentioned.

If we limited ourselves in the employment of the word delirium to this collective description of symptoms, and were willing to designate as delirious every patient who gave evidence of psychical derangement, there could be no difference of opinion as to the significance and use of the word. This is, however, not the case. In the course of time we have become accustomed to attach a special meaning to the word, aside from its general significance, and to describe a special psychopathic condition as delirium.

But even in regard to this special condition there is no unanimity among medical writers. Some regard every confusional state of mind as delirium, while others seek its particular characteristics in hallucinations, in the flight of ideas, or in incoherence of association.

In the face of this prevailing obscurity, as well as for a correct understanding of the psychopathic phenomena under discussion, it seems to me to be wise to define more accurately the conception of delirium and to restrict its use to a clearly defined condition. I believe that we are in a position to establish this boundary line on the basis of purely clinical observation. It must not be assumed, however, that we are dealing with a disease sui generis, but with a state evoked entirely by a certain complex of symptoms which, as we shall see, may arise in the most different kinds of disease.

We may frame our definition of delirium, then, in its restricted use, and founded on purely clinical lines, as follows:

*Delirium is a psychical state characterized by an abolition of self-consciousness, by an incoherence in the chain of conceptions, and by the appearance of symptoms of sensory and motor irritation.*

The abolition of self-consciousness is manifested by the total inability on the part of the patient to recog-
have not to deal with centripetal hallucinations evoked through irritation of individual cortical areas, but with visions whose origin is similar to that of dreams and which seem real only because of the suspension of consciousness and of the faculty of judgment.

Let us now consider, after having established the limits of what we mean by delirium, the points of differential diagnosis between this and similar conditions.

Maniacal exaltation first suggests itself. Although acute mania forms a disease sui generis, we must bear in mind that, like delirium, a maniacal condition may occur in the most varied diseases. The maniacal condition is characterized clinically by an extreme rapidity in the flight of ideas, which in turn is responsible for the increased irritability of the psychomotor centres.

We can best explain the appearance of these phenomena by assuming a paralysis of the higher psychical inhibitory apparatus. In accordance with this hypothesis, we find the lower impulses in a maniacal subject exaggerated in the highest degree, and the moods and passions rising and falling without check. It is not correct to assume that mania is characterized solely by a cheerful mood. At the sign of the slightest opposition, the maniac becomes wild with anger and rage, while some trifling occurrence may cause him to weep. In ceaseless alternation he shrieks, scolds, laughs, and cries.

The clinical pictures of mania and delirium may become scarcely distinguishable from each other when, in the former, the flight of ideas reaches its highest phase of development and the utterances and movements of the patient show no further trace of orderly thought. It is at this point that, in their external manifestations, the two conditions merge gradually into each other, and the consideration of the pathogenesis is of value in establishing a differential diagnosis. The maniac may be compared to a passenger in a railroad train. The landscape passes him so rapidly that he is unable to obtain any orderly impression from it; he sees nothing because he sees too much. The delirious patient, on the other hand, receives no orderly impressions because he is mentally surrounded by darkness. Now and then his mentality is cleared for a moment, but the impressions he receives are like a chain with broken links, and his perceptions are therefore obscured.

Even though the behavior of a maniac at the height of his fury appears disordered and without motive, an examination during his convalescence will always show that he was guided by certain definite delusions and hallucinations. He is cognizant of his conduct. He will say, for instance, when his maniacal exaltation has disappeared: "I was obliged to shriek to establish my rights"; "I destroyed things to anger my attendant"; "I yielded to an irresistible impulse." The preservation of self-consciousness during the attack is best evidenced by the later development of a certain responsibility and of a feeling of shame. A young woman recovering from nymphomania once remarked to me, "It is awful for me to think of the shameless way in which I conducted myself." It is frequently necessary for the physician to reassure his convalescents that their behavior was due to illness and that they were in no way responsible for it.

Matters bear a different face in the case of the delirious patient. He is absolutely unconscious of his acts. During convalescence there is either a total amnesia of the events during the attack or the memory of it exists only as that of a disturbing dream. He feels no more responsibility for what he has done than we do for the events of a dream. He is aware that his actions and emotions were the evolutions of unconsciousness and the consequences of unconscious psychical mechanism.

Whereas the moods of a maniac play an important rôle and may even lead to the commission of acts of violence, the delirious patient's mood is more uniform and is usually stamped by anxiety. Whereas in delirium it is sometimes possible to arouse the patient temporarily from his lethargic condition by calling out to him and addressing him sharply, in mania a similar procedure would only increase the exaltation, since every new impression tends to evoke further motor irritation. Still it may be possible to subdue a maniacal patient through psychical influences, not by arousing him as in delirium, but by appealing to the preservation of self-consciousness already spoken of. Threats or changes in the external relations of the patient may thus sometimes be relied upon to bring about this result. In the milder forms of mania the simple transportation to a sanatorium may have the sequel of quieting the patient, while in the case of delirium such measures lack a direct influence.

Another class of cases which may be confounded with delirium are those conditions of agitated confusion which arise from pathological passions and affections.

Strong passions, such as anger, fright, and particularly fear, may cause, within physiological limits, a considerable disturbance of the normal thinking act; but under pathological conditions, in which the intensity and duration of the passions are enormously exaggerated, and in which the psychic inhibitory apparatus, on the other hand, is functionally considerably diminished, a complete mental confusion combined with the greatest motor restlessness may appear, a condition which is seemingly identical with delirium. Such disturbances of the passions may be seen in hysteria and in most of the psychoses. They are seen most frequently and in their most exquisite development in melancholia, and are then known as melancholic frenzy and raptus melancholicus. In these instances there is also a marked cloudiness of self-consciousness at the height of the attack, which may even reach, as in a genuine delirium, total abolition of consciousness with a subsequent amnesia.

To distinguish these conditions from delirium, the origin of the attack must first be considered. In the
majority of cases, if not in all, a feeling of precordial anxiety preceeds the outbreak of melancholic frenzy, and is the cause of severe complaint on the part of the patient. Invariably, however, it is possible to demonstrate the melancholic condition from which the delirium-like state has developed.

The attack itself may be distinguished from ordinary delirium by the unmistakable feeling of fear which dominates the patient's entire demeanor. Whereas the cast of mind of the delirious patient seems to be one of indifference and may, at the most, offer the appearance of temporary alarm, every act in the state of melancholic frenzy shows the presence of the wildest despair. Despite the abolition of consciousness, a deeper impulse demands the relief of the psychical tension. With absolutely no recollection of what has happened, the patient may subsequently attempt suicide or the most horrible self-mutilation. The boundless sensation of impending fate may drive the patient to violence against his nearest relatives in the blind impulse of relieving them from pain and misery. In a state of *raptus melancholicus* mothers murder their children, husbands their wives, etc. Such inexorable demands never occur in delirium. The delirious patient never attempts suicide, nor does he show violence against others. His expression is not that of despair, and his conduct has a passive rather than an active character.

The distinction between delirium and the so-called hallucinatory confusion may offer much greater difficulty than the conditions already described. Whereas maniacal and melancholic frenzies approach delirium only in their clinical features, and fleeting transitions from one to the other occur only clinically, from the aetiological standpoint these conditions differ entirely from delirium. In many cases of confusional insanity, however, there is a certain connection between the pathogenesis and that of delirium, so that a sharp distinction between the two is impossible.

As is indicated by the name, the primary affection in hallucinatory confusion consists in hallucinations. The patient sees the most varied pictures passing before his eyes, as through a kaleidoscope. The sequence of the hallucinations is exceedingly rapid; they appeal in a disordered manner to the various centres until finally no clear mental perception is possible. The impressions of the external world, in fact, are not at all appreciated by the patient, since the hallucinations fully occupy his mind. In consequence of the ceaseless changes in the hallucinations, a complete incoherence of psychical activity supervenes secondarily. If the hallucinations are mainly of a depressing or serious character, they are followed by an ecstatic or stuporous frame of mind, while, on the other hand, anxious or cheerful hallucinations manifest themselves in the restless behavior of the patient.

Such conditions may present a striking external likeness to delirium. If they appear in the course of chronic psychoses, such as chronic hallucinatory paranoia or general paresis, the history and the further course of the disease may help to indicate the correct diagnosis. It is much more difficult, however, to reach a conclusion in a certain group of acute affections which are aetologically related to delirium; and it may even be impossible, in some cases, to decide whether a primary or a secondary incoherence of the course of ideas is present, especially as a sharp line between the two conditions can not be drawn, as already pointed out.

Another class of psychical states which resemble delirium in their phenomena are the different varieties of weak-mindedness in which we have to distinguish between congenital idiocy and an acquired dementia. In these conditions, too, we must consider a primary incoherence of conceptions, together with a limited or even an obliterated self-consciousness. These conditions of dementia are similar to delirium in their aetiology as well. They both depend upon a suspended activity of the same psychical functions, with this difference, that in idiocy and in terminal dementia the disturbance is caused by permanent organic changes, while in delirium functional disturbances only are responsible.

The distinction between confusional dementia and delirium will in reality rarely offer obstacles, since the observation of the whole clinical picture will give at once an explanation of the presenting conditions. In the majority of cases the state will be readily distinguishable from delirium in that the motor symptoms are much less marked, although even in this particular gradual transitions occur.

Finally, these conditions, marked by confusion in speech, having their origin in paraphasia and word-blindness, may be mistaken for delirium. They arise in a certain group of organic diseases of the brain, and the logical behavior of the patient as contrasted with the difficulty in speech will lead to a correct diagnosis.

Meynert has described as "pseudophasic insanity" a particular form of confusional insanity which is dependent upon word deafness and soul blindness, in which the misunderstood events of the external world evoke a certain amount of anxiety, the utterances being complicated by amnesic and paraphasic features.

The many somatic symptoms which accompany these forms or organic brain disease will easily allow the distinction between them and delirium to be made.

Having separated delirium as an independent psychopathic entity from all related and similar conditions, we will next consider the nosological rôle played by delirium, and what diagnostic and prognostic conclusions we are able to draw from its appearance. We will first consider those cases in which delirium arises in the course of an existing disease.

As is well known, delirium appears most frequently as the so-called "delirium of fever" in the acute infectious diseases. There is a marked tendency on the part of physicians to call all psychic disturbances arising in
the course of febrile diseases delirium. This is both incorrect and injudicious. In the course of a fever isolated delusions, maniacal excitation, and acute illusions appear just as frequently as delirium, and it is well to distinguish sharply between them, as they may each have a different significance. Whereas single delusions or maniacal excitation point only to a circum-scribed psychical irritation or paralysis, a genuine delirium indicates a state of inanition and demands energetic stimulation. A true delirium of fever, therefore, arises most frequently during collapse, and a muttering delirium sometimes indicates a rapidly advancing decline in vital energy.

Delirium may appear in the course of certain psychoses, and in such instances always indicates general exhaustion. It is of bad prognostic significance when it develops gradually under these circumstances, and is not infrequently the first sign of approaching death. There seems to be a special tendency toward the development of delirium in the course of functional psychoses which are complicated by some organic disease, such as a valvular lesion of the heart, a chronic nephritis, etc. Frequently delirium arises in organic diseases of the brain as a sequel to some acute lesion of the brain substance, such as minute hemorrhages, emboli, or edema.

When a delirium suddenly develops without warning in a previous seemingly healthy person, a correct judgment of the case becomes much more difficult than when it appears in the course of certain diseases. These are the cases that the general practitioner sees in relative frequency. A man who has heretofore attended quietly to his affairs suddenly becomes confused in speech, runs aimlessly about his room, reacts to no external impressions, and appears to recognize no one about him. The nearest physician is sent for and diagnosticates an acute delirium by the method above mentioned.

What is the nosological and pathological significance of such an acute delirium? Is it an independent disease, which has suddenly developed, or is it but a complex of symptoms which may be evoked by different diseases? What are the underlying forms of disease, and what means have we at our disposal to clear up the pathological condition?

The relative frequency of acute delirium induced Brière de Brismont, during the forties, to describe a special form of disease, which he called "acute delirium," and which he believed he could sharply differentiate from other similar ailments. Although, in 1879, Mendel, and later Jolly, pointed out that this is not a disease sui generis, but that acute delirium represents only a complex of symptoms dependent upon the most varied disorders, the description of delirium acutum as a special disease is found, even at the present day, in the greater number of psychiatric text-books. Let us briefly consider the various diseases which may be responsible for a so-called acute delirium and attempt, at the same time, to bring out the different points which may lead us to a correct diagnosis in every individual case.

The previous history of the patient may be of great value in our conclusions concerning an acute delirium. A history of previous epileptic attacks, for example, may without further search put us upon the track of the aetiology. The epileptic status is, as is well known, mainly characterized by a change in consciousness, and even though this change is not, as a rule, delirious in character, still it is not impossible for the clinical picture of a delirium to appear during the progress of an epileptic case. The relation of a delirium to a true epileptic attack may be varied in particulars. The delirium may directly follow or even precede an attack. In some instances the attack may be wholly absent and the delirium take its place as any other psychical equivalent of a genuine seizure. Since we have learned that epilepsy does not solely consist in the familiar seizure, but represents a permanent neurosis, cases have been observed in which a typical attack has never been seen, but in which the principal feature of the disease is represented by psychical equivalents. Delirium may sometimes be the only symptom in this class of cases, which are known as larvated or psychic epilepsy. The diagnosis must be made in these instances by the periodicity of the seizures, by the sudden disturbance of consciousness, by auriclike appearances, by the fatigue following the attack, by hereditary taint, as well as by certain neurotic symptoms showing themselves in the interval, and by carrying in mind the well-known epileptic character.

So far as the character of the delirium in these instances is concerned, it is usually on the border-line between typical delirium and hallucinatory confusion. Hallucinations are common. They are not infrequently of a religious and expansive nature; often they are of a persecutory type, and then provoke an excitement so great as to induce fear of impending death. These cases of epileptic insanity properly come under the category of hallucinatory confusion, as do a great number of cases described as epileptic delirium.

Such conditions may last as long as several hours, the termination of the delirious state being a sudden one. Usually a stupor supervenes from which the patient gradually recovers until his consciousness is restored.

The history of a recent acute infectious disease may give additional support to the correct judgment of an acute delirium. The aetiological importance of acute febrile diseases in the production of an independent psychosis has always been recognized by conscientious observers. Although our knowledge of the connection between these pathological conditions is very meagre, clinical experience has established the fact of their relation beyond all doubt.

The clinical form of the psychoses belonging to this
group is very variable, and hence the number of different types of disease described by medical writers is considerable. A common conception of this topic is unnecessarily made much more difficult by the fact that new names have been constantly introduced for the same type of disorder, so that it is believed by many that there are actually so many different diseases. As a matter of fact, the same type of disease may be based in part upon a difference of degree only, or may have partly quite different relations. While Esquirol grouped most of the disorders of this class under his démenence, in the course of time an extensive list of descriptive terms became attached to them, some of which disappeared while some are still retained in the nomenclature of the present day. Included in this group are the so-called mania gravis, the acute delirium previously spoken of, Meynert's acute hallucinatory delirium, Fürstner's acute hallucinatory insanity, the acute hallucinatory paranoia and the hallucinatory delirium of Mendel, Meyser's acute confusional insanity and asthenic delirium, etc.

How far such a subdivision into different types is justified, in what relation they stand to each other, whether there is in fact a different pathological basis for each of them or whether one or the other form is most predominant, I will not attempt to discuss here. The fact remains that in all of them the presence of delirium is most important, a circumstance which has more or less justified the tendency of calling the entire disease by the name of this condition.

The beginning of the psychic disturbance in this group may not manifest itself for weeks or months after the termination of the infectious disease. Under certain circumstances they may start with an acute delirium. If, in the course of the disease, hallucinations are most prominent, or if systematic delusions appear, or if there is a primary incoherence of thought—all these factors may offer determining points as to which type a given case shall be assigned to.

In general, the prognosis of the psychoses included in this group is favorable. Those cases, however, in which delirium constantly predominates usually represent a state of inanimation which occasionally may prove fatal, particularly in weak persons. This form is not nearly so apt to run into a secondary chronic psychosis as another type in which a regular set of delusions is developed soon after the outburst of the delirium, as, for instance, in acute hallucinatory paranoia.

Besides the acute infectious diseases, such as typhoid fever, malaria, influenza, pneumonia, pleurisy, multiple neuritis, articular rheumatism, erysipelas, scarlatina, etc., acute poisoning may produce psychoses which belong to the class under discussion. Delirium has been observed after large doses of salicylic acid, cannabis indica, belladonna, conium, and ergot. It has also been seen after a protracted use of iodiform in and about wounds, and sometimes after a lengthy administration of ether or chloroform. The inhalation of poisonous gases, such as carbonic-oxide gas, hydrogen sulphide, carbon disulphide, nitrogen monoxide, etc., may have as a sequel psychic disturbances of the kind described.

Pathological psychic phenomena beginning with delirium may develop from chronic toxic conditions induced by the abuse of chloral and chloroform, or by the habitual use of opium, morphine, cocaine, paraldehyde, absinth, and, above all, alcohol. The predominance of delirium over all other psychic symptoms is responsible for the origin of the well-known term delirium tremens, so frequently seen in chronic alcoholism. Here, too, delirium is seen only in connection with other existing conditions. The delirium itself may sometimes be only of minor importance and, indeed, may be totally absent, being then replaced by such phenomena as hallucinatory confusion or maniacal exaltation. An acute delirium in the course of chronic poisoning may arise without demonstrable cause, it may immediately follow excesses, or it may appear as a sequel of abstinence.

Chronic forms of metallic poisoning are sometimes characterized by similar psychic derangements. The principal features of saturnine encephalitis are of an acute delirious nature. Cases of so-called "transitory lead mania" have been observed frequently. Mercurial psychoses, too, are mainly characterized by symptoms of confusion. Further, those cases of lysis belong to this category, the psychical disturbances of which, as a rule, take the form of an acute delirium. A comparatively large percentage of acute delirium is formed by the puerperal psychoses. Acute delirium following even minor operations has been very frequently described. Traumatic injuries, especially those affecting the skull, may also evoke delirium.

The so-called cases of acute general paresis run their courses beginning with an acute delirium and ending fatally in a few days or weeks. These instances form a large proportion of the cases described as delirium acutum. If one examines carefully the previous history of such patients, it will almost always appear that, although the patient was in seeming good health, a series of derangements will be found which are characteristic of general paresis. The relatives will state that the patient had shown changes in character for some time past, that he had become indifferent to things which had previously interested him, that he frequently forgot important things, that his dealings appeared to be queer and without motive, etc. The autopsy in such cases shows pathological changes of some duration whose influence has remained latent, such as a chronic interstitial encephalitis, atrophy and softening in isolated cortical areas, thickening of the dura, etc.

Despite the most careful research, it may prove impossible, in a certain number of cases of acute delirium, to draw any pathological conclusions from the history. In this event, we may have to deal with a sudden attack in a previously perfectly healthy individual.
ough examination of the internal organs may give some
clew as to the origin of the disease in these cases.

I have already alluded to a twofold relation be-
tween delirium and the acute infectious diseases. I
have discussed the delirium arising during a febrile dis-
case and that accompanying a psychosis which is the re-
sult of such an ailment. I will now consider a third
group which shows a relation between the two conditions.
A person previously in perfect health may suddenly be
thrown into a state of agitation and confusion. An
acute psychosis is diagnosed and the patient is
transferred to an institution. After a while it appears
that he is suffering from typhoid fever or some other
infectious disease. Acute delirium of this nature with-
out any prodromata occurs, especially in erysipelas and
acute articular rheumatism, in typhoid fever and men-
ingitis. But even minor infectious diseases, such, for
example, as a follicular amygdalitis, have been said to
give rise to similar phenomena.

The diagnostic and therapeutic importance of a care-
ful physical examination in these cases is self-evident.
A number of cases, no doubt, starting with elevated
temperature and diagnosed as so-called "delirium
acutum," may belong to this category. The diagnosis
of meningitis usually offers no great difficulty on ac-
count of the typical symptoms on the part of the cranial
nerves. In typhoid fever, the enlarged spleen, the
quality of the dejections, and the presence of a roseola
will lead to the correct diagnosis, although these symp-
toms may sometimes be absent. The correct somatic
diagnosis of acute articular rheumatism is, as a rule,
not difficult.

The examination of the urine in a case of delirium
of acute origin must never be neglected. Although it
is a well-known fact that in the course of psychoses,
and especially during delirium, albumin and hyaline
casts may be found in the urine with no post-mortem
changes in the kidneys, yet it is not rare for an acute
delirium to start a psychosis which is dependent upon
a chronic, possibly latent, nephritis. Occasionally the
cerebral features of a uraemia may present the clinical
picture of acute delirium, although as a rule they are
characterized by epileptiform seizures or comatose con-
ditions.

The cerebral symptoms of some other forms of dis-
turbed metabolic processes may assume the form of
delirium. Now and then an acute delirium may take
the place of the familiar diabetic coma, and it may, in
fact, be the first symptom of an overlooked diabetes.

So far as the treatment of delirious conditions is
concerned, it will be determined by the therapeutics of
the underlying disease as soon as this is recognized.
Nevertheless, there are certain features of the treat-
ment to be kept in mind, especially with reference to
the symptomatic treatment of delirium itself. As I
have frequently emphasized, a true delirium is the out-
come of exhaustion, and this furnishes an indication
for free stimulation and for preservation of the bodily
strength. Abundant nourishment is consequently pri-
marily indicated. In cases of protracted delirium,
when the patient can not take his nourishment natu-
really, the use of the stomach-tube must not be neglected.
Nutritive enemata alone are not sufficient, and should
be employed only when feeding through the stomach
tube is contraindicated for one reason or another.
When there is enfeebled heart action, it is well to add
wine to the food given. If the heart's action is very
much diminished in force, subcutaneous injections of
ether or camphor should be resorted to. When the cir-
culation is very much impaired, intravenous or subcu-
taneous infusions of a saline solution are indicated.

By combating the motor restlessness, much can be
obtained in the preservation of strength. The patient
should be kept in bed if it is at all possible. The choice
of sedative remedies depends in part upon the charac-
ter of the delirium. In the cases of patients who have
feelings of great anxiety and whose clinical conduct
resembles that of melancholic frenzy, or when the de-
lirium has developed from a melancholia, subcutaneous
injections of opium or morphine are rapidly efficient
in producing quiet. If the indication to reach the
psychomotor centres directly exists, as in a case of
maniacal frenzy, hypodermic injections of hyosine or
lysoxyamine are efficacious. Subcutaneous injections
of ergotin are often followed by a good result in cases of
delirium which seem to be dependent upon congestive
conditions, such as paralytic mania, epileptic insanity,
menstrual delirium, etc. Warm baths and wet packs
frequently exert a sedative action. If the delirium is
accompanied by fever, ice applications and cold sponge
baths are useful.

Venesection is to be condemned without reserve.
The naive view that hyperaemia of the brain is alone
causative of conditions of excitation belongs to the past.
When a hyperaemia is present, it is the result, not the
cause, of the pathological process, since neuroparalytic
phenomena in the vasomotor areas evoke severe disturb-
ances in the circulation and thereby cause a cerebral
congestion. The treatment must therefore be directed
toward the stimulation and regulation of the circula-
tion, and must not include, under any circumstances,
weakening measures, such as venesection, purges, blis-
ters, etc. The fact that delirium so frequently arises
after severe loss of blood and in conditions of inanition
should be sufficient caution against the withdrawal of
blood and other similar procedures.

Delirious patients sometimes die from fat emboli
in the lungs. The injuries inflicted upon the subcu-
taneous fat in various parts of the body through the
motor restlessness of these patients formed the starting
point from which these emboli became lodged in the
pulmonary arteries, in consequence of which death
supervened. Although such occurrences are compara-
tively rare, they form sufficient indications to protect
delirious patients from injuries as much as we possibly can. Seemingly insignificant bruises may be the starting-points of grave complications, and this danger is materially increased by the fact, as we have seen, that a great number of delirious patients suffer from diseases of an infectious or toxic nature, in which the tissues are in a condition of diminished resistance.

Considering the results of our discussion, we may conclude by saying that delirium, in the sense of the definition above given, is an independent psychopathic condition which, however, does not form a *morbus sui generis*, but occurs during the course of a great many mental diseases. A correct conception of the pathological nature of this condition is of the greatest importance in diagnostic, prognostic, and therapeutic respects.

53 East Sixtieth Street.

THE IMPORTANCE OF EARLY DIAGNOSIS IN LOCOMOTOR ATAXIA, AS AFFECTED BY THE NEWER PATHOLOGY.*

BY WILLIAM BROADDUS PRITCHARD, M.D.,
ADJUNCT PROFESSOR OF MENTAL AND NERVOUS DISEASES IN THE NEW YORK POLYCLINIC.

The considerations which influenced me in selecting, upon short notice, locomotor ataxia as the neurological subject for my paper this evening were several in number and equally conclusive. Made up, as this society is, about equally of general practitioners and specialists in many fields, the subject seems, to me at least, to possess a peculiar appropriateness.

The disease is one of the most frequently observed and familiar of all the organic affections of the nervous system. During the past twelve months, in a total of one hundred and thirty-eight recorded cases of organic disease observed by the writer occurring in adults, thirteen, or about ten per cent., were in tabetics. The disease is of great interest, or should be, to the general practitioner, because of the fact that upon him depends the prompt recognition of the significance of the earlier symptoms. These earlier symptoms belong to the so-called incipient or preataxic stage of the disease, a period universally conceded to be of vital import as regards prognosis. This stage is unfortunately rarely observed by the specialist. These earlier symptoms are exceedingly varied—almost protean—in character, and may invade many or any of the domains of specialization.

It is for this reason a subject of common interest to all of us. The alert oculist is often the first to suspect its presence. The dermatologist should never lose sight of the possible relation of many cutaneous lesions to this disease. A rectal or vesical or sexual disturbance may lead to a similar interpretation at the hands of the genito-urinary expert. Lesions of joints or of the bones are sometimes diagnostic in significance to the enlightened orthopedist or surgeon. Finally, the possibility of adding an element of novelty to an otherwise old subject through the presentation of a brief résumé of the recent additions to our knowledge of neural anatomy, physiology, and pathology tempted me to accept the invitation.

Ever since the time of Duchenne, who in 1857 described it under the term progressive locomotor ataxia, we have been familiar with the clinical picture of the established disease. The existence in combination of ataxia of gait and station with abolished knee-jerks, lightening, stabbing pains in the legs, reflex iridoplegia, palsies of the ocular muscles with primary optic atrophy and disturbances of common sensation, made up a symptom picture unique in its constant diagnostic significance, not even simulated by any other known disease. Since Charcot's writings in 1879 and 1880 until recently, no assumption in neurology has been maintained with more positive aggressiveness than that the disease had an equally constant pathology, with the primary and essential location of the lesions in certain posterior columns of the cord, the said lesions being those of sclerosis. Primarily vascular, the lymph spaces were first attacked; proliferative exudation occurred with resultant overgrowth of connective tissue or neuroglia, the axis-cylinder fibres and nerve cells of the posterior cord being gradually and progressively starved and strangled into nihilative non-existence, with, of course, resultant disturbance and finally loss of correlated function in the areas of peripheral distribution. That such teaching was erroneous and vitally misleading seems true beyond question in the light of facts added within the past half decade through the investigations of Waldayer, Ramon y Cajal, Van Gehuchten, Andriezen, Marie, Hodge, Sherrington, Leyden, and others. The symptomaticatology remains, of course, largely as heretofore, but a radical change is inevitable in the interpretation of these symptoms, especially as regards their bearing on prognosis and a more rational therapeutics, as I hope to indicate later.

The discovery by Waldayer, through Golgi's stain, of the neurone as the nervous unit marked the beginning of the end of the old régime. The subsequent work of the other investigators mentioned, especially Leyden, Redlich, Marie, and Sherrington, completed, or at least materially advanced, our progress toward the doctrine of to-day.

The theory of the neurone applies to both motor and sensory units, but it is with the latter that we are especially concerned in the study of tabes. According to this theory and probable fact, the cell and its nucleus and all its processes are essentially related as a unit of nervous force and function. Motor, sensory, and sympathetic neurones are alike in this respect, though differing somewhat in less essential particulars. The neurone in which we are chiefly interested to-night belongs

* Read before the West End Medical Society of New York, April 1, 1899.
to the posterior spinal ganglia and to the homologous ganglia of the sensory cranial nerves.

The body of this neurone is flask-shaped. Its axone divides into two branches, one of which constitutes the peripheral nerve, ending, at the point of distribution, in what are known as terminal arborizations, which are brushlike expansions in the skin or muscle plates or spindles; the other branch passes inward as a posterior root to the cord.

This dorsal root is, according to Marinesco, made up of three sets of fibres: short fibres, which pass directly into the posterior gray matter or horns; medium fibres, which ascend some distance up the cord, part of them entering the posterior cornu at its middle portion, others entering Clarke's columns, these medium fibres forming the fasciculus cuneatus of Goll; long fibres, derived chiefly from the region of the corda equina and which ascend the entire length of the cord, forming the fasciculus gracilis and ending in the medulla. All three sets of fibres terminate, as do those to the skin and peripheral muscles, in brushlike arborizations. One neurone is never directly united to another, but each maintains through its body and processes its own distinct individuality. Several facts are to be noted just here which are of material significance in applying these anatomical and physiological observations to the modern theory of the pathogenesis of tabes: First, the fact that these neurone bodies are quite probably—indeed, almost certainly—the trophic or nutritional centres for both dorsal and peripheral roots, about equally distant from the terminal arborizations of both. Second, the fact that these posterior spinal ganglia are rather peculiarly vulnerable to disease because of the somewhat precarious blood supply and an exposed state of the dorsal roots from a relative poverty in myelin. This vulnerability of the posterior ganglia is especially emphasized by Redlich,* who refers to this region as locus minoris resistentiar. Third, the fact that the anatomical course and distribution of the dorsal root fibres described are in constant harmony with the older known lesions and the order of successive involvement of the columns of Spitzka and Lissauer, of Goll, of Clarke, and of Burdach, which are invariably found in tabetic autopsies in the advanced disease. Fourth, the clinical fact that the symptom picture in inipient locomotor ataxia is essentially one of sensory and neurotrophic disturbance, the motor paralysis being either a late symptom or due to a complication, such sensory disturbances being manifest in the early disease frequently in functions which are in anatomico-physiological relation to the distal termini of the neurone, either in the skin or spinal-cord arborizations. Finally, the fact that syphilis, the great aetiological factor in tabes dorsalis, exerts its malignant influence directly or indirectly through the medium of impaired nutrition is to be noted. All these facts, with others too technical for such a paper, have served as the basis for the newer pathogenic and pathology of tabes, which, in the language of Möbius, is "parenchymatous atrophy, not syphilitic neoplastic growth"; or, as it has been more elaborately expressed by Marie: "The changes found in the tabetic spinal cord are not the result of a primary systemic myelopathy; they are the expression of a progressive degeneration of the posterior root fibres. These medullary changes in tabes occur in segments, while each diseased posterior root furnishes a new contingent of degenerated fibres to the spinal cord."

This last statement, I might say just here en passant, affords an adequate explanation for the hitherto inexplicable stationary periods often noted in the progress of the disease. Through the nutritional or irritative effect of syphilis or metasyphilitic toxines, or by means of traumatism, or prolonged exposure to cold with over-exertion physically, the neurone body becomes the site of trophic disturbance which involves necessarily its processes. If sufficient in degree, an atrophy of the parenchymatous type—a neuritis probably—develops. The terminal arborizations of the processes are first affected—usually, and for the reasons mentioned, of the posterior roots. The short fibres of the dorsal roots—which make up the Spitzka-Lissauer tract—are first to yield; then the fibres of medium length, which are found in the columns of Goll and Clarke, and then the long fibres which ascend to the medulla in Burdach's column. Simultaneously the fibres of the sensory homologues of the cranial nerves may be affected. Secondarily a sclerosis of these tracts and fibres occurs. Such, in brief, is the newer pathology of locomotor ataxia. It is as yet, it must be admitted, a theory rather than a demonstration, but its foundation is so sound and its application so satisfactory in explaining many of the still while inconsistencies of the disease as to strongly recommend it and to insure its adoption as a working hypothesis.

In addition to those already mentioned, Blocq, Nogette, Wallenberg, and Ransoh have added valuable evidence in its support. Obersteiner and Redlich, while accepting the teaching that disease of the posterior roots precedes disease of the posterior columns, believe that the primary cause is a chronic syphilitic inflammation of the pia mater producing thickening which, by compressing the posterior roots, induces parenchymatous atrophy.

The apparently important objection to this theory has been urged that the posterior ganglia, while often showing disease, are occasionally found to be free, at least, of gross changes. It is well known, however, that the function of a ganglion cell may be radically altered without visible structural change, and especially does this seem probable where the function disturbed is one of nutrition. Assuming this theory to be true, at least in essential particulars, what are the correlated deductions as to prognosis and treatment in locomotor ataxia?

---

* Die Pathologie der Tuben, pp. 6, 205, Jena, 1897.
There is no reason whatever to believe that it will modify the hitherto extremely unfavorable prognosis as regards anatomical cure in the established advanced disease. It can at best better the outlook for the patient, as yet, only in those cases in which the disease is recognized in its incipiency and treated promptly and appropriately. It is reasonable to assume by analogy that if recognized with sufficient promptness in its early stages, before secondary sclerosis has occurred, the disease may not only be arrested, but an actual cure may be effected by means of appropriate treatment. Hence, the urgent and all-important necessity for a thorough study of those symptoms which from clinical experience or from a priori reasoning are known to be, or are likely to be, premonitory or prodromal of the developed classical disease.

This aspect of the subject I shall discuss from two standpoints: First, that of the significance of certain broad factors; second, the significance of certain symptoms referable to certain nervous functions.

Bearing in mind the etiological importance of age, sex, occupation, and syphilis, and also the legitimate deductions from the new theory of pathogenesis, any nervous disturbance, especially if sensory, occurring in a man between the age of thirty and forty-five, who admits or exhibits evidences of previous syphilis, and whose occupation involves exposure or overexertion, should excite suspicion sufficient to at least demand an investigation of the knee-jerk, the pupils, and the functions of the genito-urinary apparatus. If, in such a man or woman, there is a history of the characteristic prodromes of cerebro-spinal syphilis—periodical vesperian headaches associated with insomnia in the fore part of the night—then the suspicion should be strengthened and a more careful investigation follow. Dana is the only author in whose writings I have ever seen any reference to the prodromal significance of such headaches and insomnia in tabes, although I have invariably investigated as to this point in all my cases for the past five years, and in thirty-four cases have found it present in seven, all of which were syphilitic. One of the most constant statements appearing in the early clinical histories of tabesities is that of unusual and excessive fatigue, out of proportion by comparison with previous endurance to the amount or duration of exertion. The soldier gets tired on the march more easily, the sailor shirks his work from sheer fatigue, the policeman feels more and more inclined to rest on patrol, etc. (Not all resting policemen are tabetics, however.) Often in such cases there is a cachectic appearance suggestive of anemia or some dyscrasia. If not explained by other evident causes, such states of chronic quick fatigue, especially if associated with cachexia, should lead to the question of previous syphilitic headaches, insomnia, etc. The premonitory significance of certain disturbances in special nervous functions is much more important and conclusive. Such premonitory symptoms are referable to the functions of common sensation, nutrition, and special sense disturbances of cranial nerves. These I shall discuss briefly with some reference to the order of relative importance.

Common Sensation.—If the new theory as to the pathogenesis of tabes admits of practical clinical deductions of any force whatever, such deductions apply with peculiar significance to the functions of common sensation. If the evidence of nutritional disturbance of the neurone body is first manifest in the distal arborizations, we should expect among the earliest symptoms various defects in tactile, pain, and muscular sense. The facts of clinical experience are fortunately harmonious. Disturbances of common sensibility are frequent early symptoms. Of sixty-five cases investigated by Max Laehr,* with special reference to disturbances of sensibility, sixty showed early and constant hyperesthesia of the trunk with hyperalgesia to cold, and also diminution of pain and posture sense. Marinesco † found in a total of fifty cases, forty in whom there was anesthesia of the thoracic region at the nape level. There was also well-marked early tactile defect in the perineal and anal region, and especially of the scrotum. Ten of the fifty cases were of the amaurotic type, in whom disturbances of sensibility were far less constant or decided. Perhaps the earliest affected is the muscular sense in some of its subdivisions: position, weight, pressure, etc. The degree of impairment may be very slight and readily escape notice. Unfortunately, the methods employed in testing this sense are crude and utterly lacking in delicate accuracy. Pain is an early symptom. It is at times the only symptom for years, a fact to which Gray, Hutchinson, and others have called attention. Hutchinson ‡ has reported a case in which the characteristic pains constituted the only symptom for twenty-five years. Its relative constancy as an early phenomenon is well illustrated in Riley's* analysis of sixty-one cases, in thirty-seven of which it was the first symptom. In Erb's table of four hundred cases quoted by Leimbach,‖ characteristic pain was present in eighty-eight per cent. Usually and most characteristically it is in the legs and in the area of the anterior crural, less often the upper sciotic. Sciatia, especially if bilateral, is often at least suggestive. Occasionally the pains are of the upper extremity, affecting chiefly the ulnar area. Rarely it is of the fifth nerve. When located here, the teeth may be lost, dropping out one by one, and the beard may turn rapidly gray and become brittle. Rosin,* Pacetti,* and Letulle,‡ quoted in Sajous's An-

***** Revue neuroI., October 15, 1894.
nual for 1894 and 1895, have each recorded examples of the disease in which atrophy of the jaws, loss of the teeth, perforating ulcer of the mouth, or other sensori-
trophic disturbances of the fifth nerve were among the
first symptoms. Sudden stabbing pains in the rectum, often
diagnosed as rectal neuralgia, have been
noted, and many of the crises are obviously painful sen-
sory symptoms. Early loss or defect of the pain sense is
said by certain observers to be rather peculiar to special
localities, as, for example, analgesia of the popliteal space
(Bechterew), of the ulnar distribution (Bienacki), or of
the peroneal area (Sarbo). Varying degrees of an-
esthesia are often found early. Perhaps the most fre-
quent site is the sole of the foot, especially the great
toe. Patrick has described a special zone of analgesia
encircling the trunk at about the level usually of the
nipple, which he believes to be a very early symp-
tom. In all adult syphilis, in whom any of the other
symptoms mentioned are found, careful, patient exami-
nation of all forms of common sensibility should be
made.

Ocular Symptoms.—Möbius teaches that strabismus
and ptosis with diplopia, occurring suddenly in a male
adult without pain, means locomotor ataxia. Not all
neurologists are ready to subscribe to this doctrine, but
the syndrome is generally admitted to be quite common.
It was present in twenty-six per cent. of Erb's four hun-
dred cases. The third nerve is most frequently in-
volved, less often the sixth, rarely the fourth. Pupillar
changes are often early phenomena. A condition of
myosis is the rule; sometimes there is an inequality.
More significant still is the presence of what is known
as the Argyll Robertson pupil, a reflex iridoplegia mani-
fest in a loss of reaction to light with, at first, preserva-
tion to distance, usually bilateral, but sometimes uni-
lateral. A sluggish reaction to light in an adult syphili-
sit should stimulate further inquiry. An intermittent
Argyll Robertson pupil has been noted in a few cases.
Eichhorst reports two such instances, both in women,
the other symptoms being progressive. Treuapel reports a similar condition in a male tabetic. The symp-
pathetic skin pupil reflex is often lost quite early in the
disease. Anesthesia of the palpebral conjunctiva sup-
plied by the fifth is at times an early symptom. In
so-called amaurotic tabes the disease is usually first rec-
ognized through an atrophy of the optic nerve. This
atrophy is characteristically primary. Bernhardt, who
has specially studied the optic nerve changes, finds that
choked disc is very rare. Progressive blindness due to
primary optic atrophy, if associated with abolished knee-
jerks, means posterior spinal sclerosis, even though ataxic
and painful sensory symptoms are absent. This variety
—amaurotic tabes—is said to be peculiar to certain
races, notably the negro, according to McConnell.

Genito-urinary Symptoms.—All cases of sexual im-
potence dependent upon defective erection or other
motor weakness should excite the suspicion of tabes. It
is often an early symptom. Diminished sexual desire
may also be present. When impotence from motor weak-
ness is present, it will often be found that anal-
egiesia of the testicle and scrotum in some degree also
exists (Pitres's sign). Bittot and Sabrazes, Tartar-
schuff and Marianno confirm Pitres as to the frequency
and importance of defective sensibility of the scrotum
and testicle as an early sign in locomotor ataxia. This
symptom is variable, and return of sensibility in the
testicle is often coincident with renewed sexual vigor.
Some derangement in the vesical function may first at-
tract attention to the possibility of tabes. (Erb's
table, eighty per cent.). Slight incontinence, or more
frequently some tinitus or difficulty in emptying the
bladder, may lead the patient to seek medical advice.
Obstinate constipation is common in the established dis-
ease, but is valuable only in association with other
symptoms in the early stages of the disease. The sig-
ificance of rectal neuralgia is considered elsewhere.

The Reflexes.—Westphal's symptom, which consists
in an abolition of the knee-jerks, is often a very early
and always a constant sign. Certain neurologists,
among them Althaus and Buzzard, have stated that
abolished knee-jerks alone indicated the existence of the
disease, a view utterly untenable but none the less
significant as indicating the relative constancy and im-
portance of this symptom. Of Erb's four hundred
cases, the knee-jerks were lost in ninety-two per cent.*

Ostankow found abolished knee and ankle reflex in
one hundred per cent. of twenty-six cases. In cases of
suspected tabes it is of importance to note any tendency
toward progressive diminution in the activity of the
knee reflex as indicated in frequent tests. In cervical
tabes the knee-jerks are or may be normal, of course.
According to Bechterew, the superficial reflexes, ab-
dominal, epigastria, etc., are intact in pretabic tabes.

Ostankow, quoted above, found the abdominal reflexes
either normal or exaggerated in twenty-one of the
twenty-six cases studied. The remaining five were at
the paralytic stage of the disease. In certain cases in
which Westphal's zone of entry is not primarily in-
vaded, the knee-jerks are not affected. In such cases as
suggested by Babinski and Mills, it will be found that
there is a compensatory loss of the tendo-Achillis re-
ex. I assume that the methods, including those of
sensory and mental reinforcement, employed in testing
the reflexes are familiar to my audience.

Trophic Symptoms.—Some years ago a patient con-
sulted me for symmetrical perforating ulcer on the soles

---

† Loc. cit.
‡ Neurol. Centralk., p. 140, 1898.
of the feet. I was at once impressed with the fact that the ulcers were absolutely symmetrical on the planter surfaces and that there was an absence of any traumatic element as a cause. As stated by the patient, they occurred spontaneously. Tests showed the presence of Romberg's symptom, due to this ease to planter anesthesia, abolished knee-jerks, and Argyll Robertson pupil, though severe pains had not been noted. The patient had tubers dorsalis, the perforating ulcers being due to trophic impairment. Falling out of the hair, onychia, herpes, bullae, lipomata, and other cutaneous lesions are some of the early trophic phenomena which have been noted. Sudden painless swelling of joints, especially the knees and elbows, may be atrophic manifestations of the disease in its early stages. If associated with a tendency to so-called spontaneous fracture of the bones, the probability of tabes is proportionately augmented. Krojious * and others have reported examples of the disease in which an arthropyth was the first symptom.

Cries.—Among the rarer clinical phenomena of early tabes, various distressing disturbances of visceral function may occur: attacks of paroxysmal gastralgia or enteralgia, of excessive vomiting, of dysuria, of vesical tenesmus, etc., variously known as gastric, enteric, laryngeal, and bladder crises. Such attacks occurring in adults, and without other ascribable cause, may indicate the beginning of locomotor ataxia. Of Riley's † sixty-one cases, in three gastric and in three laryngeal crises were the first indications of tabes. Wolff ‡ records three examples of the disease beginning with gastric crises.

105 West Seventy-third Street.

THE
PROPERTIES OF BUFFALO LITHIA WATER.

By John V. Shoemaker, M.D., LL.D.,
Professor of Materia Medica and Therapeutics
in the Medical-Chirurgical College of Philadelphia, Etc.

Water is such a familiar body that, although we are aware of its importance in animate and inanimate Nature, ye we do not habitually, perhaps, consciously realize its positive hygienic and medicinal effects. An instinctive craving prompts the brutes to make use of the fluid as a beverage and necessity of life. Of all the tissues water is an integral constituent. The digestive fluids consist largely of water, and the digestive processes are chiefly concerned in rendering the components of our food soluble as a preliminary to absorption. Water itself is therefore a food, inasmuch as it is necessary to the life of the human organism. All this is undoubtedly true, and is set forth at length and in detail in our treatises on physiology.

Nevertheless, it may be questioned whether we are always, as physicians, mindful of the many useful purposes served by the mere administration of water in disease. It is valuable alike in the upbuilding of the body and in the removal of waste products and deleterious substances. It promotes the action of the various eliminating organs. Water has a very excellent effect upon the kidneys, and as these are the principal organs of excretion—"the common sewers of the body," as they have been termed—it possesses those virtues which belong to diuretic remedies. Not only the fluid but also the solid constituents of the urine are increased by the drinking of water. Coincident with the escape of waste matter the ingestion of water promotes the assimilation of nutritive material. As the demand for water is universal and imperative, Nature has, in most parts of the world, provided a generous supply. We are accustomed to speak of pure water, but, in the strict sense of the words, scarcely any water is absolutely pure until after it has been distilled. From the atmosphere and the soil it derives certain foreign characteristics, so that the waters of different localities differ from each other somewhat in composition. It follows, therefore, that there is no absolute distinction between plain and medicinal water. Mineral springs, impregnated with various salts and gases, abound in many regions of the world and are widely distributed in the United States. The medicinal effects of these waters depend upon the ingredients which they contain, and they are divided into different classes according to their chemical composition. Among alkaline waters the Buffalo Lithia Springs, of Mecklenburg County, Virginia, are very favorably known in this and other countries. The springs are designated as Nos. 1 and 2, and vary somewhat in their ingredients and proportions. These waters exercise an indisputable therapeutic influence far in excess of the amount of lithia and other saline constituents demonstrated as present by chemical analysis. The beneficial results which they produce can not be attributed either to the quantity of water or to the amount of the lithia, measured by grains.

Analysis shows that both springs contain sulphate of magnesium, alumina and lime, chloride of sodium, and silica, with traces of phosphoric acid and iodine. Lime is present in spring No. 2 chiefly in the form of the sulphate, while in spring No. 1 the bicarbonate predominates. The No. 2 is richer in lithia than the No. 1 spring. No. 2 also contains a considerable proportion of bicarbonate of potassium, while this salt is entirely absent in No. 1. Bicarbonate of barium, present in No. 2, is lacking in No. 1.

The water of spring No. 2 is a perfectly clear fluid, entirely destitute of any unpleasant or alkaline taste. The peculiar virtues of the Buffalo lithia water appear to be owing to the mixture of salts which they contain and, as regards spring No. 2, to the proportionately large quantity of the bicarbonate of potassium.

* Laküre Forhänd., vol. xxxv.
† Loc. cit.
‡ Laküre Forhänd., 1895.
They are likewise due to the perfect solution in which the salts are held and, consequently, to the complete absorption and assimilation which result. In the alenmic of Nature more effective solutions are produced than the laboratory of the chemist can always prepare.

An additional advantage and extremely important reason for the peculiar efficacy of the Buffalo lithia water lies in the fact that its composition approximates that of the serum of the blood; therefore it is admirably fitted for absorption into the blood current and immediate incorporation with the watery portion of the nutrient fluid. It becomes at once identical with the blood serum. These are qualities which far surpass those possessed by any extemporaneous solution of a single chemical preparation, as when a lithia tablet, e.g., is dissolved in water for immediate administration. When we speak of a dose, it is of a quantity altogether relative, and what the physician emphatically desires in a dose is therapeutic efficiency. This we have in the Buffalo lithia water.

Those who have made use of this water and carefully noted its effects have often been surprised at the results obtained from amounts so small, according to chemical analysis, of lithia and the accompanying salts. The explanation of this extraordinary activity is doubtless to be found in the conditions just adduced.

For the practical ends of therapeutics it suffices to know the properties of the agents which we employ. We are not always able to understand precisely how such properties are acquired. Abundant experience has shown that the Buffalo lithia water, by virtue of its lithia and the associated salts, is much more effective in some very important particulars than extemporaneous solutions. It exerts, for instance, a solvent action upon renal, hepatic, and vesical calculi more powerful than could be expected from a mere inspection of its chemical analysis. By sweeping uric acid rapidly out of the system it alleviates the misery of gout. It is efficacious in rheumatism, Bright’s disease, diabetes mellitus, and a number of nervous affections. These defects of metabolism are all to be traced back to faulty digestion. In a paper devoted solely to clinical observation I shall not pause to inquire into the minutia of pathogenesis. We can, however, readily detect a vicious chain of relationship between the various maladies which I have mentioned. When we extend our view and contemplate the secondary ills and complications of rheumatism, gout, Bright’s disease, and diabetes mellitus, we can more fully appreciate the virtues of a remedy which attacks the very root of the tree of morbid genealogy. “From generation to generation,” indeed, its branches extend, and what is mild in the father may become severe in the son.

The Buffalo lithia water is doubly efficient in rheumatism and gout. It dissolves uric acid and phosphatic sediments as well as other products difficult of elimination, while at the same time it exerts a moderately stimulant effect upon the renal cells, and thereby facilitates the swift removal of insoluble materials from the body. Without such action insoluble substances will precipitate in the kidneys and bladder. The intense suffering produced by stone, together with consequent pyelitis and cystitis, are avoided by prompt elimination.

Unquestionably, although the speedy removal of uric acid and other products of faulty tissue change is of conspicuous benefit, yet to prevent their formation is a service still more important. This service is performed by the Buffalo lithia water when it corrects those digestive failures which are responsible for the production of deleterious materials.

As stone is one of the most harmful and painful ultimate consequences of faulty digestion and assimilation, the solvent virtues of Buffalo lithia water constitute, perhaps, its highest merit. It has been instrumental in disintegrating large calculi of varying composition, as attested by clinical reports corroborated by chemical examination.

Nothing can afford a more direct and convincing illustration of the efficacy of the Buffalo lithia water than the recital of the histories of a number of typical cases in which it was used with advantage. I have accordingly selected certain cases in which the Buffalo lithia water was obviously influential in producing excellent results.

Case I. Acute Inflammatory Rheumatism.—A young woman, twenty years of age, complained of having had pain in her joints for the two preceding days. The knees were particularly involved. She had also experienced chilly sensations, fever, and headache. The bowels were constipated. She had not vomited, but had lost her appetite. During the night before my first visit she had suffered excruciating pain. The articular pains alternated for a while between one joint and another, and from one to the other side of the body. Finally they located themselves chiefly in the left knee, which was considerably swollen, and which the patient instinctively maintained in a flexed position.

This patient was unable to take the salicylate of sodium on account of the nausea and notable cardiac depression which it excited. As an agreeable and convenient manner of carrying out an alkaline plan of treatment, the girl was consequently placed upon the Buffalo lithia water, of which she partook freely every second hour. This water proved acceptable to the stomach from the first, and there was no difficulty in its administration. Its power was soon manifested. On the following day the patient was greatly improved. The joints were much less painful, and she had slept tolerably well during the night. She was able to make some movement of extension with her legs. At the end of a week she was entirely free from pain and, although still weak, insisted upon sitting up for a few hours.

Case II. Subacute Rheumatism.—A woman, fifty-two years of age, had for three days been suffering pain, attended by swelling and redness, in the metacarpo-phalangeal joints of the left hand; subsequently the same joints of the right hand were attacked. Thence the pain spread to the right knee and hip joints,
though the latter two were but slightly if at all swollen. About a year previously she had had a long and severe attack of acute inflammatory rheumatism. That had been her first experience with the disease. The present illness had followed an undue exposure to cold. It had been preceded by no chill, though there had been moderate fever. Some sweating had likewise occurred. Her tongue was covered with a whitish fur, and her bowels had not been moved for several days. The pain had prevented her from obtaining much sleep. There was no cardiac involvement.

In this case treatment was begun by a purgative combination in order to secure a free movement of the bowels. The main reliance, however, was placed upon the Buffalo lithia water, which she was directed to take in quantities of four to six ounces several times in the course of the day. Improvement was almost immediate. On the next day she was in less pain and her right hand was somewhat less red and swollen. She had obtained some rest during the night. On the second day the improvement still continued. The arthritic inflammation had subsided. She was able to take more nourishment than she had formerly done. On the fourth day the swelling had disappeared from the right hand. She could close both hands. She was resting well and taking more nourishment. Her tongue was coated, and it was necessary to administer another purgative dose, after which time she steadily gained, and it was not necessary for me to make any more visits.

CASE III. Muscular Rheumatism.—A short, stout, florid, and muscular man, thirty-four years of age, after lifting a heavy weight two months previously, was seized with a sharp pain in the side. A few days later he was taken ill and confined to bed for several days. His symptoms were pain in the stomach and small of the back, fever, and loss of appetite. After recovery from this attack the man seemed perfectly well for a few weeks, when he began to be troubled with muscular pains, especially upon exertion. The pains were chiefly situated in the serratus magnus, external oblique of the abdomen, and latissimus dorsi muscles. There was no continued fever, but he was apt to feel feverish at night. His skin was rather dry. Sometimes he perspired quite freely during the night, and always felt improved after the sweat. His tongue was coated with a moderately thick fur, whitish toward the tip, yellowish at the base. He was not jaundiced or sallow. His bowels acted with regularity. His appetite was poor and digestion imperfectly accomplished. His abdomen was so distended with flatus as to cause him decided discomfort. His sleep was not nearly as sound or prolonged as it had been before this attack. He frequently lay awake for hours at a time. His urine was very dark colored and felt hot as it passed along the urethra. He had no headache. He occasionally had pain in the limbs, and sometimes also in the knee, although there was no swelling in that articulation. None of the joints, in fact, were swollen. He had never suffered from inflammatory rheumatism. During the past two years, however, he had from time to time experienced joint pains without swelling.

Though this case began with an injury, there is no doubt that its subsequent course was due to a rheumatic diathesis. The continuance, the spread to other parts of the body, the turbid urine, and the prior occurrence of rheumatic twinges pointed to the nature of the affection.

In this instance Buffalo lithia water was the sole remedy employed. The man used it at the table as a beverage and drank several gullets of it between meals. The patient soon began to amend under its use, and at the end of a week had so far improved that he resumed his business occupations and discontinued attendance. The effect of the remedy was marked as regards the flatulence, which steadily and rapidly disappeared. No remedy except the water was given, as I have said, but the patient's diet was regulated. He had been a hearty feeder and had indulged freely in meats. He was also a moderate drinker.

CASE IV. Subacute Rheumatism.—A young girl, aged nineteen years, had noticed swelling of the ankles and dorsum of the foot for five days. The affected joints were painful. She was scarcely able to stand. Jarring or sudden movements caused her decided pain. At the same time she was troubled with sharp, darting pains, accompanied by some swelling, in the wrists, elbows, and finger joints. When she was brought under my observation all the tumefactions had subsided except those of the ankles. The appetite had declined. The bowels had been regular. The tongue was moderately coated. The patient felt very weak. There had been no headache, pain in the back or breast, or shortness of breath. She had not noticed any irregularity in micturition or any changed appearance of the urine. I discovered, nevertheless, that the urine deposited a considerable sediment of urates. During the five days' illness the girl had experienced a constant disposition to chilliness. She ascribed her illness to getting her feet wet.

She had previously had two or three similar attacks. She had no knowledge of a rheumatic tendency in her family.

In this case the influence of Buffalo lithia water was prompt and decided. She was directed to drink of it freely, and the urine soon became free from sediment, the pains were abolished, and she was able again to attend to her household duties. Her alvine evacuations assumed a better character and her tongue cleansed.

CASE V. Gout.—A man, fifty years of age, was a great sufferer from gout in its most confirmed form. His finger and toe joints were swollen, tender, and distended; the lobules of his ears contained chalky deposits; his digestive functions were poorly executed, and he was a picture of prematurity senility. He walked with pain and difficulty, aided by a cane, and trifling indiscretions of diet intensified his sufferings. From time to time he was subject to acute exacerbations of the disease, when the affected joints would become the seat of extreme agony. After recovery from these acute attacks he would sometimes remain considerably improved for a certain period. The disease was hereditary.

It is not necessary in this paper to detail the treatment of this severe case in all its phases. In this connection I simply desire to call attention to the beneficial effect which Buffalo lithia water had during his intervals of comparative freedom. When the patient would restrict himself to a plain and easily digestible diet, free from stimulants, and partake regularly and freely of the water, his ailment was held in check, and he experienced more comfort than he had ever thought possible. Nevertheless, like many gouty individuals, he was disposed to hearty and convivial habits, and after a period of comparative immunity he would return to the fleshpots and winebibbing which he loved. A re-
turn of pain and swelling or an acute and prostrating attack would then compel a halt, a resumption of abstemious habits, and recurrence to active treatment. When the acute inflammation had subsided the beneficial influence of the Buffalo lithia water was again manifested, and the man entered upon a new era of quiescence. Could this patient have entirely conquered his bad habits his last years might have been far more comfortable than they were. The efficacy of the Buffalo lithia water, however, was very conspicuously manifested when the patient gave it anything like a fair chance.

Case VI. Gout.—This was very similar in outline to the immediately preceding case. There was the same hereditary history, the same alternations of quiescence and exacerbation, the same chalky deposits in fingers, toes, and lobes of the ears. This patient, also male, was sixty-eight years of age, but had the advantage over the other man in that his habits were more temperate and that he yielded a fuller obedience to instructions. The results were correspondingly more favorable. The hepatic insufficiency could not, indeed, be cured, or the kidneys restored to organic and functional health, but the formation of urates was checked and their deposit inhibited, or at least decidedly lessened. Nothing more could be accomplished at the advanced stage of the disease which the man had reached. The Buffalo lithia water without doubt rendered this patient much more comfortable than he had formerly been. Had he become acquainted earlier in life with its virtues he would certainly have been spared much agony. This individual was fully convinced from his own experience of the efficacy of this treatment in chronic gout. During a series of years he relied upon it habitually, and to his use of this medicinal beverage, conjoined with his general habits of abstinence in other respects, he justly attributed the diminished frequency of acute attacks.

Case VII. Subacute Gout.—A third patient suffered from uric-acid intoxication, but in a much less extreme form than the two men whose histories have been already outlined. This person, male, aged forty years, had never been the subject of acute gout. He was troubled, however, by stiffness and tenderness of his finger joints, and occasionally had sharp but fleeting twinges in the great toes. He was the victim of migraine, which is well known to be a frequent manifestation among the gouty, if, indeed, it be not solely dependent upon the uric-acid diathesis. The man had much embarrassment of the digestive functions and was obliged to be excessively cautious in his diet if he would avoid an attack of sick headache. He was of a sallow complexion, had an habitually dirty tongue, and was much troubled by constipation and flatulence. His urine was very high colored and turbid and deposited an excess of urates upon standing.

This patient's condition was decidedly ameliorated by recourse to Buffalo lithia water. He drank it regularly and habitually, having been taught by experience its power to reduce the production and to facilitate the elimination of uric acid before it should be deposited in the tissues. In all probability the continued use of this water will prevent any of the later and graver symptoms of gout. The effect was speedily observed upon the urine, which became clear in color and devoid of sediment. Coincident with this objective improvement the finger joints became more supple and less tender. The attacks of sick headache became less frequent and less severe, while his bowels were more regular and his digestive powers strengthened. This man was an excellent patient; he was anxious to take every possible care of himself and avoid any course which might prove injurious to his health. Such people often outlive those who were originally much more rugged.

Chronic Dyspepsia.—Long-continued embarrassments of digestion are the fruitful cause of various remote ailments. That form of hepatic insufficiency which permits the production and accumulation of uric acid is the source of rheumatism, gout, and lithemia. Acute rheumatism may be ranked among the infectious fevers due to the activity of a micro-organism, but dietetic derangements certainly are very closely connected with its evolution. Chronic rheumatism is indisputably allied with notable failure of the digestive functions. The same is true of lithemia and gout. In other directions Bright's disease, gravel, and calculi, as well as diabetes mellitus, are the outcome of habitual and chronic indigestion. In all varieties of this distressing ailment, therefore, we should endeavor, by well-chosen and prompt measures, to counteract the dangerous tendencies of digestive failures. Auto-intoxication of gastro-intestinal origin is capable of assuming a variety of forms and different grades of intensity. As is well recognized, a number of diseases of the skin are produced in this manner and are never cured until their mode of origin is traced. In many cases of aggravated dyspepsia the Buffalo lithia water has exerted a very beneficial influence.

From numerous cases of chronic dyspepsia of different forms, the following have been chosen as exhibiting the good effects of this water:

Case VIII. Flatulent Dyspepsia.—A woman, thirty-six years of age, had for about two years been subject to great flatulence, coming on almost immediately after eating, causing eructations and frequently distressing attacks of palpitation of the heart. There was no edema of the limbs; she had never had kidney trouble or inflammatory rheumatism. She had the appearance of being well nourished, but her skin had rather a yellowish cast, although she had never suffered from liver disturbance or had jaundice.

In this case the Buffalo lithia water was of essential service in regulating the action of the bowels and kidneys, dispelling flatus, and relieving the palpitation. When her most annoying symptoms had been banished, the woman began to feel more hopeful, to seek the society of her friends, and to enjoy life, as she had not done for a long time.

The sallowness also disappeared and was replaced by a healthy hue.

Case IX. Flatulent Dyspepsia.—A woman, sixty years of age, had been dyspeptic for years, but for some months past had experienced an aggravation of symptoms. She is subject to "heartburn," flatulence, eructations, and sickness of the stomach, though she seldom vomits. These symptoms made their appearance from five to fifteen minutes after partaking of food. The bowels were usually constipated. Lately, also, she had been afflicted, soon after eating a meal, with feelings of
weakness, but had never fainted. She had never been troubled by vertigo. She generally had a fair appetite.

In this long-standing case the diet was regulated with a view to relieving the digestive organs, diminishing flatus, and allowing the digestive functions to become reestablished. In the management of the case great assistance was undoubtedly rendered by the Buffalo lithia water, which, according to instructions, she took freely at intervals during the day. Some medicines were given in the commencement of the treatment, but these could be dispensed with after a time, and the principal means employed were dieting and the use of Buffalo lithia water.

Case X. Flatulent Dyspepsia.—A woman, fifty years of age, had been annoyed with flatulent distention of the abdomen, nausea, and sometimes vomiting, irrespective of the food taken, not infrequently reching violently when nothing had been eaten. She was also troubled by headache, but never had vertigo. She had but little appetite. Her bowels were habitually constipated, but lately, and once six months previously, she had had a pseudo-dysenteric attack. It was attended by rather frequent passages of mucus, sometimes mixed with blood, but no chill or fever. There was no oedema. The patient never fainted, and, although she is somewhat short of breath, has not been particularly troubled by dyspepsia. She suffered also from considerable pain in the abdomen and had lost some flesh. She had never vomited blood. These symptoms began several years previously, but had been growing worse during the past year.

In this case likewise the use of Buffalo lithia water was attended by excellent results. Careful examination failed to reveal the presence of any abdominal tumor, and gastric carcinoma was excluded. The result showed that this exclusion was warranted. In addition to revision of the diet, much of the care of the case consisted in the liberal use of the water. The woman soon gained confidence in its power and followed advice to the letter. The ultimate result was extremely satisfactory, for in course of time the alimentary functions were so far restored that she was able to eat sufficiently for every purpose without unpleasant after-effects.

Case XI. Flatulent Dyspepsia.—A similar case to those already narrated was that of a woman, twenty-five years of age, who had for several months suffered from flatulence after eating, with pain in the abdomen. Her appetite was poor and her bowels rather constipated. There was no nausea or vomiting. She often had headache. She was pale and had lost some flesh. Her menses had always been regular until the last period, when an interval of only two weeks had elapsed. She had recently had some leucorrhcea, but there was no actual or developed uterine disease. Her nutrition had failed and she was anemic.

In this, as in the preceding cases, Buffalo lithia water proved of distinct service. By promoting the digestive processes it acted indirectly as a blood tonic, and this effect had been noted in other cases.

Case XII. Flatulent Dyspepsia.—A woman, forty-five years of age, had for six months past experienced great distress after meals. She was troubled principally by extreme flatulence and palpitation of the heart. The flatulence developed soon after she had eaten and lasted several hours, often as many as six or eight. The palpitation occurred very frequently, though not as often as every day. She had no colicky pains, but there was generally a feeling of soreness over the abdomen on pressure. The gaseous distention chiefly concerned the stomach, which became enormously swollen and outlined in the epigasstrum and hypochondriac regions. Some hours subsequent to a meal the swelling usually descended to the lower abdominal regions. There was no sign of decided hepatic disturbance. She had never been of a bilious habit. Her bowels were habitually constipated. She did not suffer from vertigo or headache, but had grown nervous, melancholy, and disposed to brood over every trifle. She did not sleep well at night on account of her nervousness. She occasionally had "sour stomach." She seemed to find a difficulty in eructating, though the act gave her relief. She did not have much appetite for breakfast or supper, but enjoyed a midday dinner. She feared, however, to indulge her appetite, because it led to so much subsequent distress. Her diet was of a mixed variety and the materials were good. She had abandoned the use of fried food, pastry, and coffee. This woman lived too much in the house and in too much solitude. She had no children, her husband was away at his work all day, and she associated but little with her neighbors.

Notwithstanding the gravity of the symptoms and the adverse circumstances of the case, in few instances have I witnessed more rapid amendment. She was at first ordered digestive ferments and antiseptics and her bowels were placed in a soluble condition. She was given minute directions in regard to diet and ordered to walk abroad every good day. Buffalo lithia water was prescribed and taken freely throughout the day. According to the patient's own statement, the water was of marked usefulness. The strictly medicinal treatment by drugs was soon abandoned and the woman relied exclusively upon the lithia water.

Case XIII. Bright's Disease.—Buffalo lithia water is a gentle but efficient diuretic, and in Bright's disease has a beneficial influence in promoting a flow of urine and in absorbing and carrying off dropsical effusions. This effect was particularly marked in the case of a man, fifty-two years of age, who presented himself with all the prominent symptoms of nephritic disease and whose urine contained a considerable proportion of albumin. Under the microscope an abundance of casts, mostly of medium size and of the epithelial variety, were found. There were also some granular and a few hyaline casts.

This was not a very promising case, but, nevertheless, it seemed that the kidneys were not thoroughly disorganized. The approved measures were adopted and were followed by a certain degree of improvement. The Buffalo lithia water was then added to the methods of management and could be distinctly observed to fulfill a useful purpose. It kept the kidneys and bowels active, aided in the reduction of the edema and the passage of albumin, and was instrumental in affording the patient an appreciable relief.

Grauel.—In a number of cases of gravel, both of the phosphatic and uratic variety, excellent results were observed to follow the systematic use of Buffalo lithia water. It rendered the gritty and irritating particles soft and finally dissolved them, and thus sensibly diminished pain and obstruction to the passage of urine. In these cases the nature of the deposit was verified by chemical and microscopical examination. If such affections are allowed to progress they terminate in the
formation of calculus of the kidney or bladder and the consequent establishment of calculous pyelitis or cystitis.

Cystitis.—Stone is generally referred to the operating surgeon, although a number of very remarkable instances of solution of stone within the body by the faithful employment of the Buffalo lithia water have been published. I have, however, notes of an interesting case of cystitis excited by the presence of uric acid in excess in the urine. The patient was a young man who was a great sufferer from extreme frequency of micturation, accompanied by pain, especially during the night, tenderness over the bladder, and sometimes the passage of blood. The urine contained a very abundant deposit of urates. The administration of the water dissolved these particles within the bladder and permitted a restoration of that organ to a healthy condition.

REMARKS

BASED UPON A FURTHER EXPERIENCE WITH CALOMEL IN DIPHTHERIA.*

By L. D. JUDD, M.D.,

PHILADELPHIA.

Two years ago, at Washington, D.C., I read a paper before this society, published in the Transactions of 1897, on Calomel as a Curative Agent in Diphtheria. It was based upon my experience with this drug covering a period of eighteen years.

In that paper I cited an experience with a case of inoculated malignant diphtheria in a woman fifty-five years of age, weighing two hundred pounds—the most pronouncedly malignant of any I have ever seen—due to a scratch on the finger by a child dying of this disease. That case was saved by the heroic use of calomel. Three hundred and sixty-five grains were given in thirty-five hours—twenty grains in the first dose and ten grains every hour thereafter until the characteristic action was secured. Rapid and complete recovery ensued without the slightest mal-effect due to this drug. Also in that of a child, aged eighteen months, where I gave eighty-five grains—ten grains in the first dose and five grains thereafter hourly, for sixteen hours, with similar results. Independent of these I had employed this drug in twenty-three cases of the most malignant type, forty-two pronouncedly severe, and in a much larger number, which might be called mild, though typical cases. The dose varied in accordance with the severity of each.

I have had no occasion to employ a course so heroic as in the first two named, although I have treated many malignant cases, less in degree, tempering the use of the drug to meet the requirements of each. I now believe that smaller doses of calomel, oft repeated, will exert as specific an action in the majority of cases as the larger doses related in my former paper on this subject. Nevertheless, I would feel perfectly justified in resorting to the more heroic treatment should the case seem to be approaching the moribund condition, and I would have no fear of any direful results from the drug.

Cases of diphtheria, due to inoculation, are comparatively rare. In twenty years I have had but three. Two of these occurred within a month after our meeting in Washington, and my experience with those and others has suggested these further remarks:

I was called to see a girl, aged fourteen years, suffering with a severe form of diphtheria, which responded readily to a sixth of a grain of calomel, given every half hour for twenty-four consecutive hours, decreasing the dose and lengthening the time of administration as she improved, using Marchand’s peroxide of hydrogen for frequent spraying of the throat. After securing the characteristic deflection I placed her on iron and chlorate-of-potash mixture. She made a rapid recovery. Two weeks later I was called to the younger sister of ten years and a brother of six years of age, both exhibiting a malignant form of diphtheria, as evidenced by the swollen and deeply injected fauces, engorgement of not only the post-cervical, but the submaxillary and sublingual glands also. Every precaution had been taken to prevent communication with the elder sister and contamination of the house. On the third day the mystery was solved. The elder sister had been using chewing gum when her throat was sore and probably after the patches had fully developed. As children often do, she hid it by sticking it underneath the chair seats. Her sister and brother found the bonanza and duly reeled in their discovery. In this manner they were thoroughly inoculated. I commenced by administering to each a five-grain dose of calomel, followed every twenty to thirty minutes with half a grain, also dissolving calomel triturates in warm water, and in suspension, securing the topical action of the drug in spraying the nostrils. I decreased the dose as improvement manifested itself. The nursing was faithfully done. Inside of four days they were safe. The half-grain dose was given on an average of every half hour for thirty-four doses, when I dropped to the one sixth of a grain for twenty-four hours, and to still smaller doses, until I felt that the disease was conquered. They both made good recoveries, and neither exhibited the slightest mal-effect from the calomel. It is a noticeable fact that the patient becomes stronger during the administration of this drug. There is less of local paralysis, and the so-called “heart failure” from toxemia is not liable to occur.

I have had a fair share of diphtheria in my practice since my last paper was presented in 1897, and not one patient has perished. Invariably calomel has been my mainstay. Again I state that I have never seen a case of salivation, or anemia, or any mal-effect that could be traceable to this drug in the treatment of diphtheria in the manner employed. Faithful and intelligent
nursing is of course required. There is no remedy that
to me seems so safe, and none whereby you can as
securely "feel your way." By it the nature and
the severity of the case may be early proved; should it be
only an aggregated attack of amygdalitis the one
eighth to one tenth of a grain, given every hour, with
the use of peroxide of hydrogen for spraying the throat,
will bring a comparatively early response: should it be
true diphtheria, so small a dose will bring no character-
istic action in even twenty, thirty, or more hourly
doses. In such, courage is necessary to push the
Treatment by increasing the dose, and if necessary de-
creasing the interval between doses until the charac-
teristic dejection occurs. Even before this is accomplished
improvement in the patient’s condition will be notice-
able.

By the characteristic dejection I mean the move-
ments from the bowels that have the appearance of
"frog spittle," and copious like that of the green polyps
observable in an old water trough; slight greenish move-
ments may occur before the characteristic dejection is
secured, and although improvement becomes manifest
with these, a copious "frog-spittle" stool is necessary
to prove that the limit is reached. I am well aware
of the great claims made by many in behalf of antitoxine
as a curative agent in diphtheria. The con-
sensus of opinion is far from being emphatic in
approval of its use when the advanced stage of the
disease is presented. That it has proved a success
in the doubtful, mild, and early stages I can not
question.

But in the light of my experience of twenty years
with the calomel treatment in this disease, with the
percentage of loss so insignificant, in my own as well as
in the practice of others who have tested this plan, to
change it for any other would seem like the abandon-
ment of a certainty for an uncertainty.

I wish it to be understood that I am advocating the
fearless use of calomel only in pronounced diphtheria.
Although it is one of the most valuable of all drugs
known, I realize fully the necessity of a physician ex-
ercising the greatest care and discrimination in its
employment generally. That the use of calomel has
been abused in times past there is no doubt. At the
same time we know that the hue and cry against it has
to a great extent been prompted by the so-called
edectics, who professed to have found a “vegetable calo-
mel” in podophyllin, and who later on found their
claim proved invalid; and the homeopathic sect, who
have so bitterly railed against it and at the same time
use it persistently, in high and low attenuations, under
the name of “mercurius dulcis” (a rose by any other
name would smell as sweet). Happily, the day of
bigotry and intolerance in medicine is rapidly passing
away.

THE ADMINISTRATION OF ATROPINE
IN EPILEPSY.*

By F. L. WACHENHEIM, M. D.,
ATTENDING PHYSICIAN, CHILDREN'S DEPARTMENT,
MOUNT SINAI DISPENSARY AND GERMAN DISPENSARY.

Although the employment of belladonna and its
alkaloid, atropine, in epilepsy is an old therapeutic pro-
cEDURE, the following case may be of interest as showing
an exceptionally good result from the use of atropine
and bromide, given according to a method differing from
the usual administration of these drugs:

Rosie H., the older of two children, was born normal-
ly at term. There is no neuropathic family history.
The onset of her illness dates from the age of two years,
when she began to suffer from frequent convulsions.
Treatment by several neurologists led to no permanent
improvement, and her condition had changed but little
when she first came under my observation.

She was presented to me on January 15, 1897, aged
seven years. Her mother stated that she had nocturnal
convulsions, also diurnal attacks consisting in turning
of the head and eyes, aphasia, and impairment of con-
sciousness. The diurnal seizures were preceded by slight
toothache, and the attacks in all frequently numbered
as many as eight a day. Her progress in school was
repaired by her spells of "absentmindedness" and sup-
posed inattention.

Examination showed a normal cranial conformation,
no conspicuous signs of rachitis, no paralysis of any
muscular groups; no strabismus, pupillary reactions
normal. There were no sensory disturbances. The in-
telligence was good, the child appearing rather bright
than otherwise. The thoracic and abdominal examina-
tion revealed nothing pathological; the urine was nor-
mal.

Treatment was begun, according to my usual rou-
tine, with one one-hundred-and-fiftieth of a grain of
atropine sulphate and ten grains of potassium bromide
three times a day. The attacks rapidly diminished in
number to about three a week, but the disease became
stationary at this point. Early in June I decided to
commence the treatment according to Flechsig, then
at the height of its renown. Flechsig pushes opium for six
weeks to about ten grains per diem, then abruptly changes
to bromides, two draehms a day in divided doses. The
effect of the change was far from gratifying; under opinn
the attacks soon increased to almost the original
number, and the change to bromide caused very little
improvement. This led me to think that the good re-
sults, such as they were, of the first course of treatment
were largely due to the atropine, and I resolved to intro-
duce a modification, pushing the atropine and reducing
the bromide. The new procedure was begun in Septem-
ber, and at first the success was not brilliant; when,
however, the dose of atropine sulphate had reached a
fiftieth of a grain three times a day, the attacks sud-
denly ceased. The only symptoms of atropinism had
been occasional flushing of the face and moderate my-
driasis.

On December 13th, having had no seizure of any sort
in eighteen days, she had tingling of the extremi-
ties, dryness of the throat, paralysis of accommodation,
and a scarlatiform rash. The medication was at once reduced to a sixty-fifth of a grain of atropine sulphate and two grains of potassium bromide three times a day. The reduction at first caused a slight relapse of some half-dozen attacks; then, after four weeks of immunity another reduction was made, and this again was followed by a few attacks. The last seizure but one occurred on March 10, 1898, when she was taking one one-hundredth of a grain of atropine sulphate and five grains of bromide once a day. Her only subsequent attack was on October 6th, after some weeks of total neglect of all treatment, which was then resumed; a two-hundredth of a grain of atropine sulphate and five grains of bromide being given daily, then on alternate days, then weekly, of late very irregularly. Progress at school has been steady since attacks became few in number. The last date of observation was April 19, 1899; and I consider the case at present under perfect control, if not absolutely cured.

The treatment of epilepsy, as of most obscure affection, shows the effect of empiricism in the great variety of remedies that have been used and suggested. Belladonna, silver nitrate, copper, zinc, valerian, bromides, chloral, camphor, opium, and even strychnine have been advocated; recently Adonis vernalis (Bechterew), borax (Gowers), and Solanum carolinense. Of these, the bromides have given, perhaps, the most satisfaction, but the results, especially as regards complete cure, are by no means ideal, not to speak of the unpleasant and even dangerous effects of bromism. General treatment has, naturally, had its proper place; in idiopathic epilepsy, owing to its unknown etiology, the causal indication can, of course, not be met.

The employment of belladonna dates back at least to Trousseau, who warmly recommended it, combined with salts of zinc and silver, increasing the dose to tolerance and marked improvement, then gradually withdrawing it. Trousseau's procedure has now fallen into almost complete desuetude, and is considered by most neurologists chiefly of historical interest, not even being mentioned in most of the text-books of to-day.

The chief objection usually made to the use of belladonna is that of its being a cortical irritant. Its critics seem to ignore the fact that it is to a much greater degree a peripheral paralyzant, and a stimulant to the spinal and medullary, including the vaso-motor, centres.

Among the most obscure questions of neurology is the pathogenesis of idiopathic epilepsy. The only fairly settled fact is that we have to deal with an irritation of the cells of the cortex (Unverricht). The nature of the irritant is a matter of theory. One popular view assumes that the disease is organic, depending on proliferation of the neuroglia and degeneration of the cortical cells; that the summation of this chronic irritation produces an explosive outburst, analogous to the flash obtained from a Leyden jar. To this theory we can offer many objections, aside from the fancifulness of the oft-quoted simile of the spark in the powder magazine. First, there is the fact that the cortical cells function perfectly in the interval; secondly, that the attacks, if typical, involve the whole cortex simultaneously, instead of radiating from the most affected area (cf. Jacksonian epilepsy); thirdly, that the theory begs the questions of etiology of the anatomical condition, and does not state whether the cells are at first directly irritated or only hyperesthetic, a most important point. The physiology of the nerve cell demands that at least in a chronic process hyperesthesia must precede direct irritation, or be at any rate its earliest manifestation; hyperesthesia of the nerve cell is, however, obtainable in many other ways besides the mechanical stimulus of connective-tissue growth, notably by certain poisons, such as strychnine and tetratoxin,*

This leads up to the second theory, that we have to deal with a vasomotor neurosis of toxic or autotoxic origin, reminding us at once of Traube's theory of uremia. Kussmaul and Tenner showed that sudden cerebral anaemia produced general convulsions. Marie first suggested a self-intoxication. This view so far best explains the occasional appearance of epilepsy after the infectious fevers, its frequent occurrence in chronic alcoholism, its marked hereditary and symptomatic relations to the other neuroses and the psychoses, and the record of a number of undoubted cures. We may give the course of the disease as follows: The primary acute intoxication causes one or more convulsive seizures, which, in turn, produce an abnormal irritability of the cortical cells; these becoming less resistant to even feeble excitation, we have at last the establishment of a circulus vitiosus, with a marked tendency to more and more frequent recurrences; finally, no doubt, leading to permanent changes, cell degeneration, and secondary growth in the neuroglia. The evident symptomatic indication is thus to break the above circle, even if we can not settle upon the toxic agent.

On this pathogenetic basis we may explain the action of the bromides and atropine as follows: The bromides diminish the sensibility of the cortical cells, which have become hyperesthetic to variations in the blood supply; atropine stimulates the vasomotor centres, thereby making the blood supply more uniform. In the early stages of treatment bromides are useful to dull the irritability of the cortex until the proper vascular tonus is established. When that point has been reached, they are of less importance and may be reduced or withdrawn.

Neither the bromides nor atropine can in any way meet the causal indication. If the disease depends on a passing intoxication, these drugs will suspend the destructive action of the epileptic seizures until the materia peccans has ceased to act; if there is a permanent

* It is of interest to observe that in the circulation the poison of tetanus causes cortical hyperesthesia, while applied to the cortex locally it is a direct irritant.
cause, as seems to exist in the majority of cases, our treatment will naturally be at best only palliative.

A CASE OF

TYPHOID AND MALARIAL FEVERS.

By W. H. GERMAN, M. D.,

Morgan Park, Ill.

On the 6th of August, 1898, Mrs. M., aged thirty-six years, American, was taken with rigors followed by fever. The diagnosis at first was obscure, but blood test showed typhoid to be present concurrently with malaria. The malarial fever was of mixed type, but more nearly approached a double tertian than any other. The case ran a five weeks’ course and the patient appeared to be convalescent when, after an interval of two weeks, the chills and fever returned and the temperature showed again the typhoid course. In the relapse both typhoid and malaria were more severe than in the initial attack, the temperature reaching 105° F. in the axilla, and showing less disposition to yield to treatment. Cold baths were used systematically, the strength was supported by food and stimulants by the stomach and by the rectum, iron, arsenic, and guaiacol were administered, and quinine was given in the form of the sulphate in capsule, in solution, and in WARBURG’s tincture, in gradually increasing amounts. During a period of twenty-eight days 1,470 grains were given, an average of fifty-two grains and a half daily, the largest amount in twenty-four hours being a hundred and thirty-five grains. Under these unusual amounts of quinine cinchonism was not extreme. The mind was not more dull than is common in typhoid, nor was the hearing more affected. Under the largest doses, the sight, which in health was impaired, failed entirely, but improved as the quinine was lessened, and is now nearly in its usual state.

Therapeutical Notes.

The Treatment of Gonorrhœal Rhinitis in Infants.—De Stella (Belgique médicale; Giornale internazionale delle science mediche, May) recommends penciling the nasal passages with a two-per-cent. solution of protar-
RÖNTGEN-RAY INJURIES.

Either by personal observation or by reading, physicians have now become somewhat familiar with the serious injuries that occasionally result from Röntgen-ray examinations. It is customary to speak of them as "burns," perhaps from the appearances of the persistent sloughy ulcers in which they are apt to culminate. But burns are universally recognized as injuries due to heat or to the contact of corrosives. A burn occurs at the very moment that the heat is applied, although there may be secondary lesions of slow development; as for the burn itself, it is produced instantly. On the other hand, the injuries that result from exposure to the Röntgen rays are slow in making their appearance; usually, according to Dr. Daisy M. Orleman, the "period of incubation" is from ten to twelve days, and in Dr. Orleman's own case, reported in the Medical Record for July 1st, it was twenty-one days. Hence it is futile to argue that these injuries are not due to the action of the Röntgen rays because Röntgen declares that they "have no calorific effects." Whatever may be the agent that gives rise to these frightful injuries, it certainly is not heat, although a burning sensation may be felt at the time of the exposure. Probably the lesion is the result of paralysis, more or less complete, of the trophic nerves of the area involved.

There are several points in Dr. Orleman's case that are worthy of mention, besides the length of time that intervened between the exposure and the occurrence of the first symptoms of trouble. Some of them are the following: The severe pains, which often prevented sleep and were not readily controlled by local analgetics and anaesthetics, but often called for the internal use of morphia; the fact that local treatment proved powerless to check the lesion until prolonged rest in bed was enforced; and the fact that finally, when skin-grafting was resorted to, the grafts "took" on tissue that looked gangrenous. But the point that seems to us to call most for comment is the fact that Dr. Orleman's ten months of suffering were wholly unnecessary, for the simple reason that the Röntgen-ray examinations (there were three of them) were themselves utterly uncalled for. A fracture of the femur had been recovered from, and the limb was in every way perfect, but one of the surgeons concerned in the case wished to have the rays applied, for what reason is not stated. We believe that, in view of the injuries that sometimes result from their employment, it is wrong to resort to them unless there is a reasonable presumption that their use will reveal some important feature of the case that would otherwise elude recognition; and our belief is that cases in which this is true are comparatively rare. Unfortunately, the point has been raised in at least one malpractice suit that the surgeon was guilty of neglect because he had not made an X-ray examination of the patient. We are firm in the opinion that the profession should with all its might repudiate this proposition, if the prospect is that it will be held to be generally applicable in cases of fracture.

We are quite aware that there are practitioners of large experience in Röntgen-ray observations, men for whose professional attainments and acumen we have the utmost respect, who declare that there is no danger in such examinations if they are conducted with proper precautions, but we confess that of this we are not convinced any more than we are satisfied by the declarations of eminent men that chloroform is as safe an anaesthetic as ether. Still, we recognize how difficult it is to restrain enthusiasts and those who can not bear to admit that others have done what they have omitted to do. We adjure such persons, however, to observe the precautions in their X-ray examinations that experienced observers have recommended, for example, those formulated by Dr. F. H. Williams, of Boston (cited by Dr. Orleman), as follows: Place the Crookes's tube two or three feet away from the patient when the fluorescent screen is used, and three feet or more away from the plate in taking Röntgen-ray pictures; and, as suggested by Tesla, interpose between the patient and the tube a thin screen of aluminum grounded by being connected with a proper wire to the gas pipe.

THE RELATION OF THE SOLDIER'S DRESS TO HEAT APOPLEXY.

LIEUTENANT-COLONEL MCCARTIE, of the Indian Medical Staff, contributes to the Indian Medical Gazette for June a most interesting communication on The Cause and Prevention of Heat Apoplexy in the Army, and one which will have special force for us in regard to our troops now serving in the tropics.

Colonel McCartie first combats, and we think satisfactorily, Dr. Sambon's views, published over a year ago in the British Medical Journal, that "heat apoplexy" is not caused by heat, but is an infective disease. He points out that soldiers and civilians work
under such different conditions as to dress as to account
fully for the prevalence of the disease among soldiers,
while civilians working under a higher temperature are
almost exempt. The latter wear a thin twill cotton
shirt, light, loose cotton trousers, cool socks, cool light
shoes, a light gossamer coat, worn open, and a thick
pith hat, coming down the neck, and carry a thick um-
rella; while the soldier wears clothing unnecessarily
warm and so buttoned up and strapped down that the
air can not circulate about his body, the evaporation of
the perspiration can not go on, and thus Nature’s heat-
regulating mechanism is thrown out of gear. The con-
sequences are distress, fatigue, exhaustion, fever, and
heat apoplexy!

Colonel McCartie’s observations are based upon con-
siderable experience, especially during the hot-weather
campaigns of 1895 and 1897. He noticed that most of
the men attacked by heat apoplexy were very warmly
dressed, most of them wearing flannel shirts, and many
even thick woolen undervests as well.

One piece of evidence recorded is very striking.
In a front-line campaign in 1897 sufficient coolies could
not be obtained, and part of the baggage had to be car-
ried by native soldiers in plain clothes. Before the end
of the march, says Colonel McCartie, nearly all the men
in the ranks were utterly exhausted, and some of them
had heat apoplexy, while their comrades doing duty as
bearers and carrying a much heavier weight, but dressed
in their own loose, light, rational dress, were not the
least distressed.

Colonel McCartie condemns the belts and straps
which go over the coat as the worst part of the soldier’s
dress, and advises doing away with them all. He rec-
ommends a loose Norfolk jacket with four pockets, loose
trousers with two pockets in front and two behind, and
a loose twill cotton shirt with two pockets. To these
might, if necessary, be added a light knapsack capable
of carrying the contents of the haversack and the
greater part of the ammunition. A hook could be fast-
tened in the jacket for the water bottle, and a frog at-
tached for the bayonet.

The accommodation afforded by the pockets would
do away with the necessity for belts, straps, and
pouches; while, on the march, the knapsack would ac-
commodate all the ammunition and food needed.

To sum up, the rational attire for soldiers serving
in tropical climates would be light, loosely made gar-
mets of very porous material, and an entire absence of
straps, belts, pouches, etc. The soldier is not dressed in
parade order for fatigue duty, and campaigning is
fatigue duty in the highest degree.

THE INFLUENCE OF PREGNANCY ON THE TEETH.

Our old text-books of obstetrics generally contained
a warning to the effect that, if a pregnant woman sub-
mitted to the extraction of a tooth, she ran the risk of
abortion as the result; and really, so far as the sys-
tematic works show, we have advanced but little beyond
this in our knowledge of the influence of pregnancy
on the teeth, although it is hardly to be doubted that
the dentists could give us a good deal of information on
the question. Considering the barrenness of our own
literature in the matter, we are glad that it has been
made the subject of particular investigation by M. Ter-
rier, in a Paris thesis.

M. Terrier’s conclusions are thus summarized in the
Presse médicale for June 3d: In a great number of
women pregnancy has a very decided influence on dental
caries. It is particularly toward the end of the first
month that toothache is apt to occur, and in many cases
it is repeated toward the close of gestation, in the
eight or ninth month. The progress of caries is more
rapid during pregnancy than at other times, the sensi-
tiveness of the teeth is heightened, they are more fri-
able, and their chemical composition undergoes certain
modifications. The dental affections that may arise are
attributable to two sets of causes, local and general.
Among the local causes are gingivitis, a changed com-
position of the saliva, and acid regurgitations from the
stomach. Among the general causes are (1) morbid
systemic conditions and disorders of the digestive, the
urinary, or the biliary apparatus (the last mentioned
giving rise to a form of self-intoxication termed by M.
Pinard hépatotéromie gravidique), whence there result
nutritive affections of the tissues in general and of the
bones and teeth in particular; (2) a heightened im-
pressibility of the nervous system, giving rise to dental
neuralgia and odontalgia, which are further aggravated
by the gingivitis with its passive congestion, whereby
the pulp is, so to speak, strangulated in its cavity, be-
coming the chief cause of toothache.

The general disorders of the pregnant woman place
her at a disadvantage in the struggle of her teeth
against the progress of caries; the production of sec-
ondary dentin, which normally fills the dental canals
and serves the pulp as a barrier against caries, is dimin-
ished, and a portion of the necessary calcium salts is
diverted to the formation of points of ossification in the
fetal skeleton.

To a certain extent it is possible to prevent these
affections of the teeth, and certainly it is highly desir-
able to make the attempt. A minute examination of
the mouth and teeth at the outset of pregnancy is im-
EDITORIAL ARTICLES.

perative. Every trace of tartar should be removed; if there is gingivitis, it should be treated; caries also should be treated, but care must be taken not to fatigue the patient. It is almost always practicable to fill cavities. The old caution about extraction, dating back to Antoine Petit, in the seventh year of the first French Republic, should be observed, especially in the case of very nervous women. Systematic care of the mouth should be taken during the whole course of pregnancy and lactation.

THE ARMY MEDICAL DEPARTMENT IN THE PHILIPPINES.

The medical department of the army has been severely and very unjustly criticised during the past twelve months, chiefly by critics without any practical acquaintance with the difficulties attendant on, and the peculiar conditions incident to, campaigns in foreign countries, especially tropical. It is, therefore, with great gratification that we learn through the Boston Medical and Surgical Journal for July 6th that Captain S. S. Long, an assistant adjutant-general in the British service (and, we may add, formerly instructor of the army service corps at Aldershot), in an elaborate report on the United States army administration in the Philippines, published in the Journal of the United Service Institution of India, after freely criticising all the other departments of the army, speaks in terms of the highest commendation concerning the medical department, and praises the equipment and administration of the hospitals. "The health of the troops was extraordinary," he says, "and the subject of constant remark. If the spirit of the troops was excellent, it was even surpassed by that of the medical branch, who, in spite of inadequate and defective transport facilities and many other difficulties, always had their hospitals as complete and efficient as human ingenuity could make them." This commendation is especially noteworthy, inasmuch as in the British service, more perhaps than in any other, has it been the fashion with quite a large majority of the "combatant" officers to run down the doctors.

A MIGRATORY RENAL CALCULUS.

The remote sequelae of a deep-seated abscess are apt to be beyond our ken. An illustrative case is recorded by Dr. Babacci (Durante’s Festchrift; Centralblatt für chirurgen, June 17th). A woman was operated on for an abscess of the left side. The wound healed quickly, but four years later it opened again and was found to lead directly to the kidney. When pressure was made on the abdomen, pus issued from the fistula. The latter closed under treatment with drainage, frequent irrigation, and the injection of tincture of iodine. Then, three years subsequently, after an injury, a fistula formed in the iliac region. An operation resulted in the discovery of a calculus beneath the quadratus lumborum. Its exterior consisted of phosphates and carbonates, but it contained a nucleus of oxalates and urates. It is added that the tissue surrounding it was suggestive in appearance of the cortical substance of the kidney.

A BAD MOVE IN THE FIGHT AGAINST "CHRISTIAN SCIENCE."

Last week a meeting was held in the Waldorf-Astoria Hotel to consider a bill to repress the "Christian Science" practice of medicine in the State of New York. The "Christian Scientists" themselves, being invited to be present, practically managed the meeting, and it is just as well they did, for we quite agree with the New York Times when it says: "Of course, no such law could ever be passed; of course, it couldn’t be enforced if it were passed; and, of course, it would do more harm than good if it were passed and enforced." What we want is a rigid enforcement of the present medical-practice law.

INFANTILE SPINAL PARALYSIS AND RHEUMATISM.

An "epidemic" of infantile spinal paralysis, said to be the twelfth on record, has lately been reported by Dr. Simonini (Gazzetta degli ospedali e delle cliniche, 1899, No. 43; Centralblatt für innere Medizin, June 17th) as occurring in a region in which acute articular rheumatism was prevailing, and he thinks there was some connection between the two diseases. This opinion, he suggests, derives some support from the known relation of chorea to acute articular rheumatism. Five children were affected, varying in age from sixteen months to four years. Although one of them had had rheumatism a year before, the part attributed to that disease in producing the paralysis seems to need confirmation.

"ABDOMINAL CELEIOTOMY."

A few years ago the word celeiotomy, to denote abdominal section, was brought forward with great insistence on the part of its advocates that it was a better word for the purpose than laparotomy. We have never thought so, and the word does not seem to be universally recognized as fully signifying abdominal section, for it is getting to be more and more common to see the expression "abdominal celiotomy" in print.

THE SENSE OF SMELL IN MEN AND WOMEN.

It seems that among the many points of advantage possessed by women over men is that of having a more delicate faculty of distinguishing odors. Apparently the fact has been clearly established by M. Toullie and M. Vaschide, who recently reported to the Paris Academy of Medicine (Indépendance médicale, June 14th) that their conclusion to this effect rested upon nearly twenty thousand tests.

GESTATION IN A RUDIMENTARY UTERINE HORN.

A Russian physician, Professor Sanischin, who reports a case of this sort (Vratch, 1899, No. 5; Deutsche Medizin-Zeitung, June 22d) is to be credited with having made the diagnosis largely on the strength of the history of the case. The woman stated that several months before she had felt foetal movements, but that for a month they had been wanting, although her breasts had become enlarged and had secreted milk. The uterus was deflected to the left and was not enlarged. Its cavity communicated, through a broad pedicle, with a mass on the right larger than a man’s
head. No fetal movements or heart sounds could be made out. Laparotomy was performed, and the diagnosis shown to be correct.

THE TRANSPLANTATION OF TENDONS.

This ingenious procedure appears to have a wider range of utility than has generally been supposed. At a recent meeting of the German Society of Surgery (Wiener medizinische Blätter, June 29th) Dr. Vulpius, of Heidelberg, reported eighty cases in which he had resorted to it. The cases in which he has found it serviceable include recent and old injuries of tendons, muscles, and peripheral nerves, infantile spinal paralysis, spasmodic paralyses, occasional instances of paralysis due to apoplexy, and many such congenital deformities as clubfoot and flat-foot.

HEREDITARY PTOSIS PALPEBRARUM.

A curious case of ptosis of the eyelids transmitted for several generations, the series having apparently been started by a "maternal impression," is recorded by Dr. Munden, of Hamburg (Deutsche medizinische Wochenschrift, 1899, No. 16; Wiener klinische Wochenschrift, June 29th). A pregnant woman became affected with ptosis in consequence of fright. She gave birth to a daughter who had bilateral ptosis. This girl grew up and had three children, one of whom, a boy, had congenital ptosis. The boy, now grown to manhood, has a child with the same anomaly.

TETANUS IN NEW YORK.

For the last week or two traumatic tetanus appears to have occurred with far more than its usual frequency in New York, and there is probably a certain element of truth in the idea that the injuries produced by the explosives incidental to our barbarous way of celebrating the Fourth of July are particularly prone to be followed by the disease. At all events, if the small boy can be made to imbibe that notion, some good may result—some saving of life and little mitigation of the misery to which the sick are now doomed on that day.

URTICARIA DUE TO ODOROUS EMANATIONS.

The multiplicity of the exciting causes of urticaria was exemplified at a recent meeting of the French Society of Otology and Laryngology (Progrès médical), when M. Joal reported three cases, one provoked by the preparation of aromatic essences and preceded by spasmodic sneezing, rhinorrhea, and vertigo, and the other two, associated with asthma and hay fever, occasioned by iodiform, carbon sulphide, the rose, the lilac, and the hyacinth.

THE UNACKNOWLEDGED CLIPPING HABIT AGAIN.

We are usually very careful in our proof reading, but occasionally errors will slip in. In our issue for May 27th we published a minor editorial on Macular Atrophy of the Skin. The printer unfortunately converted the word "macular" into "muscular," which error, we regret to say, escaped our notice. We have had frequent occasion to protest against the use of clippings from our columns without acknowledgment. We trust that the St. Louis Medical Gazette for July will be none the worse for annexing our editorial, error and all. We must again remind journals that it is our intention to drop from our exchange list such as we find repeatedly guilty of this gross discourtesy.

SQUIBB'S EPHEMERIS.

A new number of Dr. Squibb's Ephemeris of Materia Medica, etc., has appeared, dated July, 1899. It is of interest chiefly to pharmacists, for it deals entirely with acetic acid as a substitute for alcohol in extracting the active principles of certain drugs, on which subject it presents two papers.

THE YELLOW FEVER IN SANTIAGO.

It is very gratifying to learn that on Tuesday of this week a surgeon-general of the army received official information that yellow fever was on the decline in Santiago, and that the troops were free from it.

ITEMS.

A Statue to Baron Lavrety.—On June 9th, at the military hospital, Val-de-Grâce, a bronze statue by Falguière of the great military surgeon was inaugurated by General Zurinden, governor of Paris.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, cholera, and plague were reported to the surgeon-general during the week ending July 15, 1899:

Changes of Address.—Dr. Edward Blaise, to No. 145 Himrod Street, Brooklyn; Dr. H. T. Eichacker, to No. 774 Bushwick Avenue, Brooklyn; Dr. J. L. Waldie, to No. 406 Hart Street, Brooklyn.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 8 to July 15, 1899:

Chimelcek, Joseph F., Acting Assistant Surgeon, United States Army, will proceed to San Francisco for duty.
Echeverria, Rafael F., Major and Surgeon, United States Volunteers, will proceed to Guines, Catalina, San Felipe, San Antonio de los Banos, Madurga, San Nicholas, Jaruco, and Guanayaj for the purpose of ascertaining the sanitary conditions and amount of destitution in each of the places named, and also to visit the Red Cross hospitals at these points.
Henry, Joseph N., Major and Surgeon, United States Volunteers, recently appointed, is assigned to the Thirty-first Infantry, and will proceed to Fort Thomas, Kentucky.
Howard, Deane C., Captain and Assistant Surgeon, United States Army, will proceed to West Point, New York, for temporary duty.
Kean, J. R., Major and Surgeon, United States Volunteers, is relieved from further station at Fort Warren, Massachusetts.
Reynolds, F. P., Captain and Assistant Surgeon, United States Army, will report to the chief surgeon of the department for duty as attending surgeon and sanitary inspector at these headquarters.
Richards, William E., First Lieutenant and Assistant Surgeon, United States Army, is granted sick leave of absence for one month with permission to return to the United States and apply for an extension of three months.
Russell, Frederick T., First Lieutenant and Assistant Surgeon, United States Army, is relieved from duty at Ponce, Puerto Rico, and, upon arrival of Ashford, Bailer K., First Lieutenant and Assistant Surgeon, United States Army, will report at Humacao, Puerto Rico, for duty.
Wells, G. M., Captain and Assistant Surgeon, United States Army, will proceed to San Juan and take command of the United States General Hospital at that place.

The following changes in the stations and duties of officers of the Medical Department are ordered: Bratton, Thomas S., Captain and Assistant Surgeon, United States Army, to Camp Meade, Middletown, Pennsylvania, and report to the commanding officer, Nineteenth United States Infantry, for duty, to accompany that regiment to Manila; Cleary, A. P. D., Acting Assistant Surgeon, United States Army, will proceed to Fort Screven, Tybee Island, Georgia.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Week ending July 15, 1899:

Baldwin, L. B., Surgeon. Detached from the Key West Naval Station and ordered to New York for treatment.
Brodick, R. G., Passed Assistant Surgeon. Granted leave of absence for six months on account of sickness.
McClanahan, R. K., Assistant Surgeon. Detached from the Naval Hospital, Philadelphia, and ordered to the Key West Naval Station.
Steele, J. M., Surgeon. Detached from duty in connection with the recruiting rendezvous at Baltimore and ordered home to await orders.
Young, L. L., Passed Assistant Surgeon. His sick leave is extended three months.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending July 15, 1899:

McAdam, W. R., Assistant Surgeon. Granted leave of absence for fourteen days.
Ramus, Carl, Assistant Surgeon. Relieved from duty at the Cape Charles Quarantine Station and directed to proceed to Havana, Cuba, and report to Surgeon H. R. Carter for duty.
Foster, J. P. C., Acting Assistant Surgeon. Granted leave of absence for thirty days.
Stearns, W. L., Hospital Steward. Relieved from duty at New York (Stapleton, Staten Island) and directed to report to the Medical Purveyor, New York city, for duty.
Allen, G. C., Hospital Steward. Relieved from duty at Baltimore, Maryland, and directed to proceed to New York and report to the commanding officer for duty and assignment to quarters.
Peck, F. H., Hospital Steward. Relieved from duty at the Egmont Key Detention Camp and directed to proceed to Baltimore, Maryland, and report to the commanding officer for duty and assignment to quarters.

Births, Marriages, and Deaths.

Born.
Oppenheimer.—In Tampa, Florida, on Monday, July 3d, to Dr. and Mrs. L. S. Oppenheimer, a son.

Married.
Cater—Hutchins.—In Jamaica Plain, Massachusetts, on Thursday, June 29th, Dr. Douglas Aymar Cater, of New York, and Miss Meriel Whiton Hutchins.
Graves—Jenney.—In West Somerville, Massachusetts, on Saturday, July 1st, Dr. Frederick Clinton Graves, of Bridgeport, Connecticut, and Miss Eva Channing Jenney.
Ring—Taylor.—In Arlington Heights, Massachusetts, on Friday, June 30th, Dr. Arthur Hallam Ring and Dr. L. Barbara Taylor.
Maddox—Spring.—In Tedrow, Ohio, on Thursday, June 29th, Dr. William Hedrick Maddox and Miss Ada Florence Spring.
VACCINATION IN ITALY.

To the Editor of the New York Medical Journal:

Sir: In his presidential address to the American Medical Association Dr. Joseph M. Mathews had the goodness to call mad people, misguided people those who have not the good luck to be among the believers in the preventive power of vaccination against small-pox. It is not surprising to hear such language from fanatics; in fact it is most common to see ignorant men make use of similar vulgar expressions; but it seems to me almost incredible that the president of such a powerful association as the American Medical Association in his address showed himself so enthusiastic in his belief as to forget that respect which is due to his colleagues who do not have the same blind faith.

It may be that we antivaccinationists are "mad" and "misguided," but I feel that we are far more correct in our expressions, although we do not believe, but are quite sure, that vaccination is one of the most wonderful and most harmful mistakes into which the medical profession has ever fallen. I can assure you that if I am a madman, my madness is very contagious, because all my pupils for several years have become as mad as I am, so that several thousands of medical men in Italy are suffering now with the same kind of madness.

One of the most prominent characteristics of madness is shown in illusions and hallucinations which are accepted as fundamental truths. Now, let us see what are the main facts about vaccination and small-pox in Italy:

Italy is one of the best vaccinated countries in the world, if not the best of all, and we can prove that mathematically. All our young men, with not many exceptions, at the age of twenty years must spend three years in the army, where a regulation prescribes that they must be directly vaccinated. The official statistics of our army, published yearly, say that from 1885 to 1897 the recruits who were found never to have been vaccinated before were less than 1.5 per cent., the largest number being 2.1 per cent. in 1893, and the smallest 0.9 per cent. in 1892. This means, in the clearest way, that our nation twenty years before 1885 was yet vaccinated in the proportion of 98.5 per cent. Notwithstanding, the epidemics that we have had of small-pox have been something so frightful that nothing could equal them before the invention of vaccination. To say that during the year 1887 we had 16,249 deaths from small-pox, 18,110 in the year 1888, and 13,413 in 1889 (our population is 30,000,000) is too little to give a faint idea of the ravages produced by small-pox, as these 18,110 deaths in 1888, etc., did not happen in the best educated regions of our country, but only in the most ignorant parts, where our population live just as they lived a century ago—that is, the mountainous parts of Sardinia, Sicily, Calabria, etc. Among the great number of little epidemics which produced the 18,110 deaths mentioned, I will only note the following: Badolato, with a population of 3,500, had 1,200 cases of small-pox; Guardavalle had 2,300 cases with a population of 3,500; St. Caterina del Jonio had 1,200 cases (population, 2,700); Capistrano had 450 cases (population, 1,120); Maverno had 1,500 cases (population, 2,500). All these villages are in Calabria. In Sardinia the little village of Larcru had 150 cases of small-pox in one month (population, 800); Perugia, too, in one month had 541 cases (population, 1,400); Ottana had 79 deaths from small-pox (population, 1,000), and the deaths were 51 at Lei (population, 414). In Sicily 440 deaths were registered at Nota (population, 18,000), 200 at Ferla (population, 4,500), 370 at Sontino (population, 9,000), 135 at San Covo (population, 1,600), and 2,100 deaths at Vittoria (population, 2,600)! Can you cite anything worse before the invention of vaccination? And the population of these villages is perfectly vaccinated, as I have proved already, not only, but I obtained from the local authorities a declaration that vaccination has been performed twice a year in the most satisfactory manner for many years past.

Vaccinationists were not puzzled by these facts, and with the greatest certainty they asserted that this enormous number of deaths was due to want of revaccination. Happily, in Italy we are able to prove that revaccination has not the least preventive power. I only give a few figures: During the sixteen years 1882—97 our army had 1,273 cases of small-pox, with 31 deaths; 692 cases, with 17 deaths, happened in soldiers vaccinated with good result, and 581 cases, with 14 deaths, happened in soldiers vaccinated with bad result. This means that of a hundred cases of small-pox, fifty-four were in persons vaccinated with good result, and only forty-six in those vaccinated with bad result, and that the death-rate among those vaccinated with good result was 3.45 per cent. and only 2.40 per cent. in those vaccinated with bad result.

Vaccinationists say that when vaccination does not "take" the operation must be repeated, because no result means no protection given. Now, we see that soldiers not protected because vaccination did not "take" were less attacked by small-pox than those duly protected by the good result of their revaccination; and that the death-rate in those vaccinated with good result was greater than among those in whom vaccination did not "take".

Our vaccinationists did not lose their extraordinary courage before these facts, and they objected that they could be accounted for by considering that during the years before 1890 vaccination was not well performed. I can not understand this objection, but accepted it, and have limited my analysis to the last six years, during which the only lymph used in all our army has been animal lymph, exclusively furnished by the government institute for the production of animal lymph. The results are the following: The total number of our soldiers during these five years was 1,334,025, of which 783,605 were vaccinated with good result, and 450,420 with no result. In the first the cases of small-pox were 153—that is, 1.95 to every 10,000 soldiers, while in the others the number of cases was only 45—that is,
0.99 cases to every 10,000 soldiers. The "duly protect- ed" soldiers were attacked by small-pox in a proportion double that among the "unprotected" soldiers.

As you see, these are official statements, extremely trustworthy, because the official statistics were made in a country where and at a time when no one thought that it was possible to raise a doubt against the dogma of vaccination. In our country we have no league against vaccination, and every father thinks that vaccination is one of his first duties; for these reasons no bias could exist against vaccination in making these statistics. I could continue for a long while to quote similar facts, but I wish to call your attention only to the two following ones: During the three most terrible years of epidemics that we have had in Italy lately (1887, 1888, and 1889) the death-rate from small-pox among our people of the same age as the soldiers (twenty, twenty-one, and twenty-two years) has been 21 per 100,000, and it was 27.7 during the worst year (1888). In our army the same death-rate during nine years (1867-75) has been 20 per 100,000, and it was 61.3 during the worst year (1871).

In consequence of our young men being obliged to spend three years in the army, it happens that after the age of twenty years men are by far better vaccinated than women, and, if vaccination did prevent, after the age of twenty small-pox should kill fewer men than women. But in fact just the reverse has happened. I give here the statistics of the three years 1887, 1888, and 1889 as the ones of greatest epidemics, but all the other years give the same results:

<table>

</tbody>
</table>

After these facts I would most respectfully ask Dr. Joseph M. Mathews if he can show that in considering them I have lost my mind. At any rate, I do not consider it correct for a medical man to make use of such language against other medical men, however few, who have the only fault of considering facts as they are, and not as one wishes they should be.

The progress of knowledge has for its principal base truth and freedom, and I hope that in the name of truth and freedom you will publish these observations, badly expressed in a language that is not my own, in your most esteemed journal.

Charles Ruta, M.D.,
Professor of Hygiene and of Materia Medica in the University of Perugia.

DEATH FOLLOWING STRicture OF THE URETHRA.

To the Editor of the New York Medical Journal:

Sir: The fact that large, young, strong, and apparently healthy men are not always the subjects par excellence for surgical operations was clearly and forcibly demonstrated in the case of a man weighing something over two hundred pounds, of hale and hearty appearance, who found his way into the Ensworth Hospital on May 23d suffering from stricture of the membranous portion of the urethra. The man in question was employed by the St. Joseph Telephone Company as lineman, which position he held up to the time he entered this institution, a fact which goes to show that he was apparently an able-bodied man. When he appeared at the hospital it was found that the stricture was so tight that the smallest catheter could not be introduced. He was allowed to remain undisturbed until the next day about twelve o'clock. He was then put under the influence of an anaesthetic, when the surgeon managed to pass a small-sized sound, which was followed by larger ones until about a No. 20 French was introduced. This allowed the urine to flow uninterrupted, and all trouble was supposed to be at an end.

During the next day or so the penis, scrotum, testicles, and surrounding tissues began to swell and continued to do so until quite large proportions were assumed. In the mean time the patient's temperature became abnormally high, which tended to lessen the man's vitality. After a time a small gangrenous spot was noticed on the left side of the penis, which rapidly spread until a mass reaching half around the organ and two or three inches long sloughed away. This process continued until almost the entire organ was destroyed. Finally a urinary fistula developed in the perineum, and later on one on the side of the penis about an inch from the glans. These led to urinary inflammation, with the result that the tissues of the perineum and penis became infiltrated with that fluid. From this time on the patient grew rapidly worse until death relieved his suffering early in June.

The question which naturally arose was, What could produce such a wholesale and rapid destruction of tissue in a man who seemed only a few days before to possess unquestioned vitality? Of course, diabetes melitus and alcoholism were thought of. Examination of the urine failed to show any signs of the former trouble, and the patient stated that he had abstained from alcoholics for a year or more before his stricture. It might have been that a diabetic diathesis was present, or that he misinformed us as to his former habits. That there was some condition which rendered the patient incapable of standing traumatism there is no room to doubt.

It seems to me that such a case as the foregoing demonstrates the necessity of a careful examination and critical study of patients before surgical operations, especially in such a grave affection as stricture in the membranous portion of the urethra, to the end that we may avoid inflicting all unnecessary traumatism. There should be an equilibrium maintained between the amount of work done and the ability of Nature to successfully cope with the injury inflicted.

Edward A. Glasow, M.D.,
Interne at Ensworth Hospital.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By Arthur N. Taylor, LL.B.

XXVIII.

CIVIL MALPRACTICE, INCLUDING GENERAL LIABILITY OF PHYSICIAN TO PATIENT.

(Continued from page 106.)

Refusal by Physician of Proffered Assistance does not Increase his Obligations.—A physician, having assumed charge of a case, the degree of knowledge, skill, and care which the law requires him to possess and
exereise is not altered by the fact that he refuses the proffered assistance of other medical men. His refusal in such a case is simply an implied declaration of his ability to treat the case properly, and its effect is neither to increase nor decrease the degree of knowledge, skill, and care which the law makes it his duty to have and exercise.*

Admission of Inadequate Skill.—If, on the other hand, the physician frankly informs the patient that he has not sufficient skill or experience to treat the particular case or injury, the degree of skill that can reasonably be required of him is thereby materially decreased.† Such an admission will not, however, relieve the physician from liability when he continues his services with the assistance of another physician or surgeon. In a case of this sort the liability is a question of fact to be determined by the jury, who, in arriving at their conclusion, must determine whether there was such a degree of ignorance or unskillfulness displayed as to justify holding the defendant liable to the plaintiff in damages, notwithstanding his admission. In the case of Lorenz vs. Jackson,‡ the plaintiff had been injured by being struck by a piece of steel in a break-hammer, which passed through two pairs of trousers and buried itself in his left leg above the knee. After receiving the injury he rode about a mile on a handcar, and then walked about five hundred feet to his home. Soon afterward the defendant arrived and examined the wound, but was unable to find the piece of steel; he announced that the wound was of a serious character and that he did not regard himself as sufficiently experienced in surgery to properly treat the case, and advised that a more skilled and experienced surgeon be called in. Another doctor was accordingly secured. Together the doctors administered ether, and the physician last summoned probed for the piece of steel, widening the wound in the limb, and thereafter applied bandages. The doctor first summoned remained with the patient all night, administering to him hypodermic injections of morphine and atropine. The treatment continued for about eight days, when it was discovered that dry gangrene had ensued. A third physician was then called to take charge of the case, who soon determined upon and performed an amputation. Much evidence was given upon the trial respecting the treatment of the patient by the first two physicians called, but what that evidence was the report of the case does not show. The judge, upon submitting the case to the jury, charged them in effect that “if the practitioner frankly informed the patient of his want of skill, or if the patient is in some other way fully aware of it, he can not complain of the lack of that which he knew did not exist.” Notwithstanding, the jury returned a verdict in favor of the plaintiff, assessing his damages at three thousand dollars. This verdict the supreme court refused to disturb.

Liability for Negligence of Student.—It has been observed that a physician and surgeon is entitled to compensation for the services of his apprentice or student practising under his direction. As a logical result, he should be held responsible for the negligence or want of skill in such assistant. This has been held to be the law in England,§ and this case will probably be considered an authoritative precedent in America.

† Sherman and Redfield on Negligence, § 607.
‡ Lorenz vs. Jackson, 88 Hun, 200.
§ Hancke vs. Hooper, 7 C. and P., 81.

Must follow Established Practice.—One of the rules which the law strictly enforces for the protection of the public is that when there is an established practice or mode of treatment for a particular disease or injury the physician must conform to professional custom and adopt the established treatment, but will not be permitted to experiment without incurring liability for resulting injuries.*

The reason for the rule, also an indication of the extent to which it will be enforced, is well expressed in the case of Carpenter vs. Blake,† when the court said: “Some standard must be adopted; otherwise experiment will take the place of skill, and the reckless experimentalist the place of the educated, experienced practitioner. If the case is a new one, the patient must trust to the skill and experience of the surgeon he calls; so must he if the injury or the disease is attended with injury to other parts, or other diseases have developed themselves, for which there is no established mode of treatment. But when the case is one as to which a system of treatment has been followed for a long time, there should be no departure from it, unless the surgeon who does it is prepared to take the risk of establishing by his success the propriety and safety of his experiment.

“The rule protects the community against reckless experiments, while it admits the adoption of new remedies and modes of treatment only when their benefits have been demonstrated, or when, from the necessity of the case, the surgeon or physician must be left to the exercise of his own skill and experience.”

The question of when a method of treatment is considered sufficiently settled or established as to be the only safe one for a physician to adopt has given the courts some trouble. This question is, however, one rather of fact, to be determined from the evidence of expert witnesses, than of law. In the case of Slater vs. Baker and Stapleton,¶ decided in England in 1767, the evidence showed that a surgeon and an apothecary were employed to treat a leg which had been broken and set. In treating this leg they rebroke it and applied a new instrument. The evidence of experts was to the effect that when the callus had formed to any degree it was bad practice to rebreak the leg; and that in the present case the callus must have formed to such a degree as to render the operation improper and contrary to recognized practice. The surgeon who performed the operation was a man of recognized ability and high professional standing. The court refused to set aside a judgment for the plaintiff and closed its opinion by saying: “For anything that appears to the court, this was the first experiment made with this new instrument, and if it was it was a rash action, and he who acts rashly acts ignorantly; and although the defendants in general may be as skillful in their respective professions as any two gentlemen in England, yet the court can not help saying that in this particular case they have acted ignorantly and unskillfully, contrary to the known rule and usage of surgeons.”

† Carpenter vs. Blake, 60 Barb., 488.
§ Winner vs. Lathrop, 67 Hun, 511.

In the case of Winner vs. Lathrop the patient was suffering from a fracture of the radius. The defendant reduced the fracture several hours after the injury, and, so far as the evidence shows, seems to have performed the operation skillfully and in accord with
the most approved methods known to the profession. There was, however, evidence given by the defendant to the effect that the defendant directed that the injured part be bathed in a decoction of wormwood and vinegar, which the expert testimony condemned.

The injured arm was not perfectly restored to its former usefulness; the wrist remained to some extent stiff, the rotary motion of the arm was obstructed, and the usefulness of the hand was permanently impaired. For this reason suit was brought, and judgment obtained in the trial court against the defendant for fifty dollars. The supreme court, upon appeal, was of the opinion that no unskillfulness in the treatment of the arm had been shown, and that application of wormwood and vinegar to the injury, even if proved, was not such a departure from approved medical treatment as to justify a recovery against the defendant.

A case rich in instruction upon the point in consideration is that of Jackson vs. Burnham.* The plaintiff was suffering from phimosis, and the defendant, instead of siting up the prepuse, applied a flaxseed meal poultice, which aggravated the malady and accelerated gangrene, and resulted in the destruction and loss of the organ. Upon the trial of the case the trial judge instructed the jury, among other things, that: "If you find from the evidence that this defendant, in the treatment of the plaintiff, omitted the ordinary or established mode of treatment, and pursued one that has proved injurious, it is of no consequence how much skill he may have; he has demonstrated a want of it in the treatment of the particular case, and is liable in damages." The supreme court, upon review of the case, criticised this instruction, saying, in effect, that as an abstract proposition of law it was not absolutely correct, because it did not give an opportunity for the exercise of enlightened judgment in cases involving doubt, or where there was reasonable ground for difference of opinion as to the nature of the disease and the proper mode of treatment. But as applied to the present case, where the evidence showed by a strong preponderance that the disease from which the plaintiff was suffering was phimosis, and that the proper method of treating this condition is to slit the prepuse to the corona, relieving the tension or strangled condition and permitting the restoration of circulation, the instruction could not have misled the jury to the prejudice of the defendant.

In cases of this sort the court held that the test by which to determine whether a physician is bound to follow a particular mode of treatment for a given condition is whether or not that mode of treatment is upheld by a consensus of opinion of the members of his profession. The court said when the method of treatment is so upheld, "it should be followed by the ordinary practitioner; and if a physician sees fit to experiment with some other mode, he should do so at his peril."

For the purpose of more fully illustrating the application of the rules and principles of law laid down in the foregoing pages of this chapter the character of the defense of the defendant in this case will be examined. The defendant admitted that the proper remedy for phimosis was that testified to by the expert witnesses and above given; but he denied that the plaintiff was suffering from phimosis. He maintained that the swollen condition of the organ was the result of an ulceration of the urinary canal and that the treatment prescribed for him was proper for such a condition. The defendant's counsel urged that, admitting the defendant had erred in diagnostating the case and that the true condition was phimosis, then the error was one of judgment for which the defendant could not be held responsible.

Upon the trial of the case, after all of the evidence was introduced, the trial judge properly instructed the jury upon the duties of the physician: that he must possess ordinary, etc., skill and knowledge; that he must use ordinary care and diligence; and that in all cases of doubt he must use his best judgment; but that in cases where competent physicians might honestly differ as to the nature of the disease the defendant should not be held responsible for an error of judgment reached by the exercise of due skill and care, etc. While the records of the case do not show that there were any special findings of fact returned by the jury, yet the conclusion necessarily follows from their verdict, which gave the plaintiff damages to the amount of five thousand dollars, that they found, from the evidence submitted, either that the defendant was incompetent or, if competent, that he did not exercise ordinary skill and care in diagnostating the case; and that the case was not one in which competent physicians might honestly differ in their opinion as to the nature and extent of the disease after making a careful and proper examination.

(To be continued.)

Pith of Current Literature.

The Nature of Rheumatic Arteritis.—M. Blot (Gazette hebdomadaire de médecine et de chirurgie, June 18th), in a thesis at the faculty of Lyons, states as a result of careful investigations by autopsy that arterial complications in acute arthritic rheumatism have for their cause an embolus, and are not directly due to the rheumatism itself. The embolus originates from clots or intraauricular vegetations.

The Late Mr. Lawson Tait.—The Journal de médecine de Paris for July 2d contains one of the most admirably appreciative notices of this distinguished surgeon that have come under our notice.

The Effects of Baths, Massage, and Exercise on the Blood Pressure.—Edgecombe and Bain (Journal of Physiology, vol. xxiv, p. 48; Edinburgh Medical Journal, July) have used the haemodynamometer of Oliver to observe the influence of various physical agents on the blood pressure in man. To ascertain the effects of temperature, cold, warm, and hot water baths were employed; also the Turkish, Russian, and sitz bath. The action of the needle bath and douches were also studied, as well as saline, sulphur, and artificial Nauheim baths. Wet and dry massage, and severe and gentle exercise, complete the list. The conclusions are as follows: 1. Cold baths of plain water raise the arterial pressure and lower the venous pressure; after reaction, the arterial pressure falls and the venous rises. These results seem to depend on change in the peripheral resistance. The cold needle bath has a more pronounced effect. 2. Hot baths lower both arterial and venous pressure. This seems due to dilatation of all the vessels and consequent increased capacity. 3. Turkish baths lower the arterial

* Jackson vs. Burnham, 20 Colo., 532.
and venous pressure to a still greater extent. The pulse rate is greatly increased. Besides the vascular dilatation, there is probably a diminished output of the heart. 4. Sulfate baths at warm temperatures lower the arterial pressure to a greater extent than plain water baths at the same temperature. The artificial Nauheim bath is still more active. 5. Dry massage lowers the arterial pressure and raises the venous pressure, provided the abdomen be not massaged too vigorously; if this be done, a rise occurs in both. The factor affected seems to be only the peripheral resistance, the heart output remaining unchanged. The first result is due to peripheral relaxation, the second to dispersal of blood from the splanchnic area to the systemic circulation. 6. Warm water plus massage (Aix douche) lowers the arterial and raises the venous pressure to a greater extent than dry massage. 7. The effect of exercise on the blood pressure depends on the severity of the work done. In all forms there is an initial rise. If the exercise be mild, so as not to affect pulse and respiration, a fall occurs; if severe, the initial rise becomes increased. After exercise a fall takes place. The venous pressure is raised all through.

Typhoid Fever among our Soldiers in the Late War.

—Dr. Victor C. Vaughan (American Journal of the Medical Sciences, July), who was appointed in August, 1898, by Surgeon-General Sternberg, in conjunction with Major Walter Reed, United States army, and Major E. O. Shakespeare, United States army, on a commission to inquire into this subject, says:

"To summarize concerning the so-called protracted malarial cases reported by the regimental surgeons, we will say that, in our opinion, practically all of these were typhoid fever, and the following are our reasons for this opinion:

1. The uneven distribution of the so-called malaria among regiments encamped side by side gives us cause to suspect that these were not malaria.

2. Some of the surgeons who failed to record their cases as typhoid state in their comments that typhoid fever prevailed in the regiment. One illustration of this may be of interest. From April to November there were in the Sixth Ohio, according to the recorded diagnoses in the monthly reports, only two cases of typhoid fever. Notwithstanding this fact, the acting assistant surgeon in charge at that time writes in the October report the following statement: 'The health of the command is improving. The prevailing disease that has caused the sickness we have had is typhoid fever.' And yet the September report showed only one case of typhoid fever, and the October report showed only one case, and this one case was one and the same patient carried from the August report on to the reports for September and October.

3. The results of several hundred blood examinations show that malaria was a very rare disease among the troops that remained in the United States.

4. Malaria as it exists in this country is easily controlled by moderate doses of quinine. All the so-called protracted malarial cases in our camps were treated with large doses of quinine and were not improved thereby. Consequently, we must conclude that the diagnosis given these cases was erroneous.

5. The mortality of the so-called protracted malarial correspond with the mortality of typhoid fever, and furnishes most positive proof that these cases were not malarial."

As regards the question of changing camps, Dr. Vaughan says:

"The influence of change in location of camps upon the continuance of typhoid fever is exceedingly interesting. We have not investigated this subject as thoroughly as we hope to do. At present, however, I think that we can give the following conclusions:

(a) A regiment thoroughly infected with typhoid fever does not lose the disease when it changes its locality, even when it goes to a perfectly unobjectionable site and leaves all its sick behind. Evidence of this is shown in the history of the whole of the Second Division of the First Army Corps when it moved from Chickamauga to Knoxville. At Chickamauga Park this division became thoroughly saturated with typhoid fever. After reaching Knoxville, and notwithstanding the fact that the camp site was probably as fine as any in the world, the water supply unobjectionable, the nature of the soil suitable for the digging of sinks, surface drainage good; notwithstanding all of these advantages, typhoid fever prevailed more largely than it did at Chickamauga. It is altogether probable that the clothing, blankets, and tentage of the men became thoroughly infected with the typhoid bacillus. When a regiment becomes saturated with typhoid fever, change in location alone is not sufficient to get rid promptly of the disease. We believe that it will be necessary in such a case thoroughly to disinfect clothing, blankets, tentage, etc.

(b) If a regiment be moved before the infection has become marked, typhoid fever may disappear or at least decrease.

(c) Apparently a sea voyage of some days or weeks might rid a command, not widely infected with typhoid fever, of the disease. We have some illustrations of this in the troops that went to Cuba. For instance, about half of the First Volunteer Cavalry went to Cuba, while the other half remained at Tampa. Before the departure for Cuba, and while the regiment was all together, typhoid fever appeared, and its prevalence was confined to those companies that went to Cuba. Apparently this part of the regiment lost its typhoid fever on its way to Cuba, while the part that remained behind became badly infected.

(d) A regiment thoroughly infected with typhoid fever does not lose the disease or lessen the number of cases after a short voyage at sea. This was illustrated by the Nineteenth Infantry, which, after becoming thoroughly infected with typhoid fever, was transported to Porto Rico. The progress of the disease apparently was not in the least retarded by this voyage."

Measuring the Intensity of the Heart Tones.—Dr. Albert Abrams (Medical News, July 8th) thus concludes a paper on this subject: 1. The loudness of the heart tones may be measured by testing the distance to which they are transmitted from their clinical point of auscultation. 2. This may be determined by two methods. The first method consists of measuring the distance to which the heart tones are propagated along definite routes on the chest. The second method consists of introducing between the stethoscope and the chest wall a soft-rubber rod of varying length, the tones gradually becoming less distinct as successive rods of increasing length are employed. 3. Of the two methods the latter is by far the more accurate, although this by no means represents an ideal attainment. 4. The employment of either method does away with memory in observing the progress of the strength of the heart in-

PITH OF CURRENT LITERATURE.
individual cases, and enables us to distinguish more easily any accentuation of the tones. 5. The order in which the tones can no longer be heard is as follows, beginning with the weakest tones: First aortic, first pulmonary, second tricuspid, second mitral, second aortic, second pulmonary, first tricuspid, and first mitral tone. 6. Until a universal stethoscope is employed we can not hope to make the method of measuring the heart tones of general application, but must content ourselves with the application of the method to individual cases. 7. The first point beyond the hepatic region where the cardiac tones are no longer audible marks the lower border of the liver.

Celluloid Thread for Sutures and Ligatures.—Pagenstecher (Deutsche medicinische Wochenschrift, April 6th; Medical News, July 5th) takes a good thread, boils it for half an hour in a one-per-cent. solution of soda, washes it in boiling water, and then dries it between sterile compresses. He then soaks it in a solution of celluloid, and passes it again through the same solution. Afterward it is sterilized by steam under pressure, and preserved for use either dry or in an alcoholic solution of bichloride of mercury. Such threads have a smooth surface, they never tangle, they can not absorb secretions, and are easily tied. For three years Pagenstecher has used these celluloid threads, to the exclusion of silk, and the use of catgut for ligatures has been greatly reduced. The results have been of the best, and the saving in expense considerable.

Epilepsy from Abuse of Coffee.—Marburg (Wiener klinische Rundschau, May 21, p. 337; Medical and Surgical Review of Reviews, June) records the case of a previously healthy married woman, aged forty-five years, with a good family history, who acquired the habit in 1893 of eating daily from five to ten drachms of roasted coffee beans, while continuing to drink coffee in the ordinary way. Tremors of the hands and spasms followed, and finally in 1897 genuine epileptic convulsions, in which urine was passed unconsciously, and the tongue was bitten. These occurred regularly every fortnight or oftener. In 1898 she was unable to obtain the coffee, and though at first the fits continued, since the end of November, 1898, there has been only one, and that after an indiscretion in diet. Syphilis, hysteria, and the menopause could be excluded as causes, and since alcohol, mercury, lead, ergotin, chloroform, ether, and other poisons can produce epilepsy, it seems very probable that the writer’s view that the coffee was the cause of the attacks is correct, especially since the number of the fits decreased when the coffee was relinquished.

Obscure Case of Abdominal Pain Complicated by Morphinism.—The Medical Age for June 25th publishes the following graphic description of a case by the late Dr. William Pepper:

“The face, if rightly read, may be an open answer to many an otherwise insolved problem. We can learn much from a man’s expression if we will but look. For example, here is a man whose face at once attracts and interests me, which will prove a clue. I think, to the solution of his hitherto unexplained case.”

“We are told that he has been unable to work for nine years, and for the major part of that time has been in bed, owing to an illness which has lasted during that period of time. But his complaisant, contemplative, half-contemptuous look is not that of a man worn out by chronic disease. In the first place, there are not many chronic troubles which last ten years, and when they do they make their marks as they go along; the patient is slowly broken down; piece by piece his strength, his courage, and those properties which go to make up what we call ‘self,’ are slowly sapped. This man’s face does not present such a story; it is rather the face of a man who has been accustomed to see his case baffle his doctors, without experiencing the depressing influences of an organic trouble. Then, again, he tells a different story from that which a chronic case would relate. Let us hear it.

“At the outset, nine years ago, he began to experience paroxysmal attacks of pain in the upper zone of the abdomen. These pains grew worse through the attacks, until they were somewhat relieved by spells of vomiting. Later the pain became more or less constant, with these occasional exacerbations. The matters vomited were very offensive, liquid, blackish in color, but so far as I can determine not known by microscopic examinations to be blood or bile. The pain, he says, ran across his body from the left just below the edge of his ribs, and was of such a sharply defined nature as to make him suspect that some animal was darting to and fro. His skin at the same time seemed to be hyperesthetic; with this, occasionally, he had periods when he suffered from retention of urine. From the account it would appear that the catheter did not carry off the water until the bladder walls were stimulated to action by outside irritation, such as punching or kneading.

“The patient went into a hospital after being under treatment for two years outside without relief. Here, to quiet his intense paroxysmal pain, he was given morphia; this practice was kept up for eighteen months, until he was in the habit of taking five grains hypodermically in the twenty-four hours. Since dismissal he again experiences the pain, though less intensely, and has reduced his morphine-taking. As he lies here to-day he tells us he is here to do or die, that he is willing to undergo any operation or course of treatment, however rigorous, if he is only relieved. As we approach this case, let us first endeavor to analyze the course of his trouble. We seem to have three stages: First, the developing disease; secondly, morphia-eating; and thirdly, a decrease in morphia-taking with a recurrence of the original pain; for he confesses to the occasional use of that drug, which, after careful examination, we find is taken pretty regularly during the day.

“It has always been my experience that when morphia has been given for any length of time for the relief of pain, there occurs a mimery of the disease on the gradual withdrawal of that drug—a simulating of the original aches and pains, which imitate the real complaint so cunningly that it is often difficult or impossible to decide their true source. We will remember this element when we reach the history of the trouble again. The fact complicates an originally obscure case.

“It was not nephritic colic; here the pain is anterior, in the renal region, along the course of the ureter, and the passage of a calculus is common. Vomiting is common, but the case is clearly not of this sort. Neither is it hepatic; true, it is abdominal, but there never have been jaundice or gall-stones found after careful search. This reduces it to gastralgia or enteralgia. The position of the pain and the other signs all point to the stomach as the original seat of the trouble.

“This was true probably nine years ago, but what of the condition to-day? It will be necessary to elimi-
nate the morphine element before we can study the case successfully or intelligently. Without demonstrable organic lesion, it is never safe to attempt to diagnosticate any case into which such a factor enters. Then we will study what is left; new symptoms will probably rise up which will furnish good data.

"In conquering the morphine habit it is necessary for the physician and patient to work hand in hand; there must be forbearance and patience and sympathizing encouragement on the one side, and conscientious, earnest endeavor on the other. In such a condition of things it will be possible to overcome this dread trouble, but it can be done in no other way. Simultaneously with this will be established a tonic nutrient treatment, a regular diet, and good moral control. Electricity may be used to tone up the system. Some analgetic which is not an anodyne will be given, such as antipyrine. We will not attempt any lavage or nephrectomy, however, until we clear up the case sufficiently to make a diagnosis reasonably certain and not mere guesswork."

A Case of Spinal Sarcoma.—Dr. G. T. Howard (Intercolonial Medical Journal of Australasia, April 20th), in a paper read before the Medical Society of Victoria, records a case which seems to offer a rather unique opportunity of studying compression of the cord, due to causes not tuberculous and not traumatic. A girl, aged fifteen years, shop assistant, complained of severe pain in the lumbar region about the middle of November, 1898. After two days' rest she was able to resume work, but was not quite well, being very easily tired; could not stoop easily, but hold herself very straight, and was pinned in the back by any little jar or jolt.

On December 24, 1898, she again complained of severe pain in the region of the right loin. She was admitted to the hospital on January 13, 1899. She then complained of spinal lumbar pain, as well as pain in right loin and right leg. The pain began on the right side about the sacro-iliac joints, and then went to the back, hips, right knee, right tibia, and right ankle. There was very severe pain in the back and right leg on the slightest movement; she was unable to move her feet; there were no symptoms pointing to involvement of the brain, or digestive, circulatory, reproductive, or respiratory systems. The temperature was 99° F.; the pulse 104, feeble and regular. The urine was scanty, 1.015, very offensive, alkaline, containing a trace of albumin, but no pus. The right ankle and knee were tender, but not red. A bedsore about two inches in diameter, over the sacrum, had been there about a week. Her previous health was good. There was no family history of tuberculosis and no history of spinal injury.

A week later (January 22d) there was complete motor paralysis of both lower extremities; no patellar nor plantar reflexes; complete anæsthesia of the right foot; some loss of sensation in the right leg; sensation in the left leg practically normal; retention, occasionally incontinence, of urine, and incontinence of feces. She did not feel either urine or feces coming away, but felt the bed wet afterward, or smelled the faces. One inch from the spine in the upper lumbar region, on the right side, was an apparently semisolid, elastic swelling, about three inches by two inches, raised not more than a third of an inch from the surface, smooth, uniform, and not tender on pressure. No spinal tenderness could be elicited. The temperature had varied from normal to 101° F.; the pulse was about 100; the urine still alkaline.

The most probable diagnosis seemed to be tuberculous disease of the spine, causing transverse myelitis, and compressing the cord. The swelling was supposed to be a thick-walled lumbar abscess, and it was decided to explore.

On February 7, 1899, Mr. F. D. Bird cut down on the lumbar swelling and found it to consist, not of pus, but of a gelatinous-looking material, which Dr. Mollison pronounced to be round-celled sarcoma. Mr. Bird only removed some small particles for microscopic examination. The wound healed satisfactorily, but the onward course had been steadily downward. The temperature had varied from normal to 101° F.; the pulse between 100 and 120. There was still retention of urine and incontinence of feces. The sacral bedsores had become much wider and deeper; there was also a large new one over the right hip, two inches and a half in diameter, and so deep as to expose the muscles, while two smaller ones had developed quite recently. None of these, Dr. Howard felt convinced, were due to careless nursing. There had been very rapid wasting, and the patient was then practically skin and bone. There was complete motor and sensory paralysis of both lower extremities, but no pain anywhere except just above the tumor. The urine was light straw color, 1.010, faintly acid, containing a good deal of uoccus, a little albumin, but no pus. The tumor had increased markedly in size, reaching out five inches by four that it, and was about three inches above its base. It was uniformly smooth, and mostly tense, being apparently cystic in two or three places—looking as if it were going to fungate.

Since the operation the only special treatment had been one sixth of a grain of morphine three times a day, and the patient declared she felt splendid.

This case seems to the author to be interesting, not only from its extreme rarity, but mainly from the great difficulty in diagnosis. The preliminary pains might, in addition to spinal lesions, have been due to rheumatism, colic (renal, biliary, or intestinal), appendicitis, perinephritis, sacro-iliac disease, or hysteria. Gradually all the non-spinal lesions were eliminated, and the physicians were restricted to some lesion or lesions causing, at first, local spinal pain, as well as pain along the course of the right lumbar and sacral nerves, and subsequently complete motor and sensory paralysis of the lower extremity, as well as very acute bedsores and rectal and bladder trouble. A compression involving the whole thickness of the cord, myelitis, would account for these symptoms, and the question then was, What was causing the compression? Before operation, it seemed most likely that spinal caries was the cause, and the extra spinal swelling, somewhat simulating lumbar abscess, seemed to confirm the diagnosis. Hydatid was thought possible, but not probable, and malignant disease was not thought of at all, in spite of the rapid onset. The cystitis came on with such suspicious rapidity as to justify one in looking upon it as a "trophic" lesion, rather than, as it often is, simply a result of retention. The loss of patellar reflexes was interesting, and was probably due to the fact that the reflex centres in the lumbar enlargement had been destroyed. About defecation, the incontinence admitted of two explanations—one, that the centre in the lumbar regions was destroyed; the other, that it was intact, but that fibres conveying volitional influences from the brain had been interfered with, so that reflexly voluntary bowel movements had ceased and a purely reflex act. The retention was probably due to paralysis of the detrusor, due to destruction of the reflex centre in
the cord. The first bed sore was so rapid in its onset, within a week from the time the patient took to bed, as to suggest serious disease of the gray matter of the cord.

A lesion, such as the visible tumor, would not cause all the symptoms—e. g., bladder and rectal, nor bed sore, nor paralysis on left side. Hence, there must be two lesions—one within the vertebral canal (involving the cord and its membranes), and the other constituting the now plainly visible tumor. Which was primary and which secondary remained to be seen. According to Gowers, sarcoma of the cord and its membranes is rarely secondary.

**Strychnine in Opium Poisoning.**—Dr. R. D. Pennefather (British Medical Journal, June 24th) was called at 7.30 p.m. on May 5th to see a stout lady aged about thirty-eight years. She was in a comatose state—the pulse at the wrist was imperceptible, the heart sounds were extremely faint, respiration gasping, about six to the minute, the pupils pinhole, the skin moist and warm. She had gone to bed at 3 p.m., having been nursing a friend for the previous sixty hours, during which time she had had no sleep, and scarcely any nourishment. Dr. Pennefather found beside the bed an empty glass smelling of opium. Having tried in vain to rouse her by flicking with a wet towel and vigorous friction to the limbs, he gave her a fifth of a grain of strychnine hypodermically. Almost immediately the muscles of the face and arm twitched, then she opened her eyes, and when sufficiently aroused to swallow she was given a pint of strong coffee. There was some difficulty in keeping her awake for a couple of hours. She made a rapid recovery and admitted having taken fifty minims of laudanum, as she had frequently done before. She may not have taken more, but on account of the exhaustion, the opium might have taken much greater effect. Dr. Pennefather considers this case to show what an invaluable agent strychnine is in such cases.

**Urinary Incontinence Treated by Tightening the Sphincter Vesice.**—At a meeting of the Montreal Medical Society Dr. Lapthorn Smith (Canada Medical Record, March) reported the following case: Mrs. M., aged forty years, had a very severe instrumental labor about a year previously, ever since which time she had had to wear large pads to catch her urine. Her physician was unable to stop it in any way. If she remained in bed she could hold her water for an hour or two, and then it would trickle out if she moved or took a long breath, and when she went about her work it kept running all the time, keeping her clothes wet and always smelling of urine. Dr. Smith put her on his usual tonic treatment—namely, a mixture of iron, strychnine, and phosphoric acid in full doses—and in order to observe her better took her into the Samaritan Hospital for a fortnight. A careful examination failed to detect any fistula; in fact, in the process of filling her bladder with warm salt solution the latter flowed out by the side of the catheter; there seemed to be no life in the sphincter. There were a large prococoe, a cystocele, and a lacerated perineum. Although he had seen a great many patients with this condition, quite commonly causing desire to micturate frequently, and also with a sensation as though some urine still remained in the bladder, as indeed it did, yet he did not remember to have had a case in which it caused incontinence. He therefore feared that the cure of these conditions alone might not suffice to cure her of her trouble, and he had some intention of, at the same time, shortening the relaxed sphincter. This he found was quite easy to do, when he had removed the vaginal mucous membrane to the extent of two inches and a half in length and an inch and a half in breadth. In order to tighten the sphincter he made the denudation farther down toward the meatus than usual, and, instead of drawing the edges surrounding the demuced area with a purse-string suture, as he usually did, he tightened the sphincter by means of a running catgut suture which was buried in the muscular layer of the bladder right down to the urethra. The vaginal mucous membrane was then accurately brought together over this. Hegar's operation on the posterior vaginal wall was then done, with a buried and a superficial row of catgut. This made a good support for the bladder. Fortunately, the catgut was good and the patient's tissues were healthy, so that in both primary union was obtained. The result was all that could be desired. She could cough and turn in bed from the first day without wetting herself, and at the end of two weeks she could walk about with comfort and without a single drop of urine passing involuntarily.

**Chrysarobin for Warts.**—Dr. G. W. Fitz (Boston Medical and Surgical Journal, June 29th) treated a wart on the plantar aspect of the foot with salicylic acid in collodion for three weeks without effect. He was then led from its superficial resemblance to the lesion of psoriasis, viz., bleeding points, to try a solution of chrysarobin in gutta percha. The wart was thoroughly pared to profuse bleeding and the solution applied to the denuded surface. The patient was directed to cut the surface every night and apply the chrysarobin. In a few days the pain disappeared and the wart remained diminished in size. In two weeks' time the wart was practically gone and the surface restored to its normal condition.

Since that time Dr. Fitz has applied chrysarobin in eight cases of warts similarly located which had been treated for months by salicylic acid without success. In most cases the chrysarobin produced little effect before the end of the first week, except that the pain became less and the wart did not increase; in the second week change was rapid in most of the cases, although in a few cases there was still little effect. In the third week the majority were cured. In the series of eight cases there had been no failures. Two apparent failures were traced to difficulty in paring the wart, and so soon as this was remedied by sandpapering the cure progressed favorably. Careful thinning of the surface with a sharp, fine glass-paper gives better results than paring with a knife, as the patient is less afraid of injuring himself and can more conveniently handle the paper. Chrysarobin may be applied either in a ten-per cent. solution of the ordinary gutta-percha solution or in a ten-per cent. ether solution at night, and the patient should put on an old stocking, to prevent soiling the bed clothing. Application once a day in this way seems ordinarily to be sufficient, but in obstinate cases it should be applied both night and morning. Chrysarobin seems to act not only upon the keratinized portion of the skin, but also upon the proliferated blood-vessels in the papillary central part, for both disappear and true skin is formed over the surface. No scab is thrown off, but a considerable thickness of the surface is removed in each
case by cutting and sandpapering. In one case of warts on the hand it had the same favorable effect. Experiments with chrysarobin on corns show that it has practically no effect upon them.

A New Explanation of the Origin of Choked Disc.—J. Deyl (Wiener klinische Rundschau, April 13th; Medical Age, June 10th), after much investigation, states that choked disc is the result of compression of the vena centrals retinae at its emerging point, or before, by the outer sheath of the optic nerve, which is forced apart from the nerve fibres by pressure from hydrops intervaginalis or an extravasation of blood. The dural sheath thus expanded into an ampulla, bonds and compresses the vena centrals until the circulation is partially arrested. The accumulation of fluid in the anterior portion of the space between the sheaths is caused by increased intracranial pressure, or by some occlusion of the optic foramen. This occlusion may also occur with a tumor of the hypophysis or in acoinegiala in certain anatomical conditions, in which case the choking of the nerve head is due to stagnation of lymph and consequent compression of the vein. As long as the ampulla-shaped dilatation of the dural sheath does not reach to the emerging point of the vein, "choked disc" does not occur, even with pronounced hydrops. And after the dilatation has subsided, from recession of the fluid after trephining or healing of the intraenral afflection, the expanded sheath collapses, the pressure is removed, the circulation is reestablished in the vein, and the choked disc condition is ended, but is liable to recur with a renewal of the circumstances. Tuberculous, syphilitic, and other lesions may also compress the vein at its emergence and cause the chocking. The vein is not compressed in its farther course, but rather dilated, which refutes the theory of primary edema. The writer calls attention to the new sign, the impossibility of artificially controlling the pulsation of the papillary arteries, which in many cases will distinguish a cerebral tumor from a renal affection as the cause of choked disc.

Book Notices.

The presentation of a work containing an account in one volume of the diseases of the four organs mentioned will be of great advantage to a large number of the profession throughout the country. The character of the work is of a high order, but it seems to us more a work for the specialist than for the general practitioner.

The portion of it devoted to the eye is divided into twenty-four sections by as many different authors. To this are added seven sections on the operative surgery of the eye. Finally, there are seven sections covering the subjects of color blindness with special reference to the examination of railway employees, the standards of form and color vision required in railway service, the Röntgen rays in opthalmic surgery, the practice of ophthalmic operations on animals' eyes, and the most important micro-organisms having etiological relationship to ocular diseases.

Part ii is devoted to the ear, and consists of thirteen sections by fourteen authors. It may be stated here that the "collaboration method" employed in this work demonstrates to a satisfactory degree its value and great use.

Part iii contains twenty sections on the anatomy, physiology, and diseases of the nose and throat by eighteen different authors.

This is a valuable text-book for the library of the specialist. Some of the subjects are treated somewhat too briefly, from the reviewer's standpoint, but the essential points are all here. The volume is not an easy one to handle, on account of its size, but the paper, though glazed, is good, and the typography is very good.

The second edition of this interesting work on the special surgery of the head and neck has been brought fully up to date by numerous additions to the text and by the introductory chapter on bacteriology, antisepsis, and asepsis.

The volume is divided into thirty-five chapters, with a hundred and ten illustrations. Under the head of erysipelas we note the author has failed to mention the value of cultures in the diagnosis of doubtful cases. His treatment is also, perhaps, rather too radical. After mentioning numerous drugs and methods he sums up by saying: "Nearly all of them bring some relief and ameliorate the patient's condition; but in none is the hope of a cure realized except by the subdermal method last given."

The method advised consists in a hypodermic injection of a three-per-cent. solution of carbolic acid "in front of the advancing erysipelas." We think no method justifiable which exposes the patient to direct infection into the circulation; besides, we have seen cases do remarkably well under the use of a twenty-per-cent. solution of icthyol or a strong solution of bichloride of mercury applied directly to the surface.

Again, under the head of incised wounds of the scalp, he urges the use of metallic sutures, especially those of copper wire which has been heavily plated or gilded.

We think the employment of catgut which has been properly sterilized answers every purpose and simplifies the treatment. The writer gives catgut a place, but thinks its absorption too rapid, but why should we not use heavier or chromatized gut?

There is necessarily some repetition in the book, for the different regions treated have a number of affections in common, and they are discussed separately.

The chapter on plastic surgery has a number of valuable suggestions and is rich in illustrations.

The author's description of intubation of the larynx would be improved by adopting Northrup's position.
"The position of the head should be as though it hung from the top of the head," instead of, "the head turned backward," etc.

The type and arrangement are good and make an attractive page.

One of the best of this excellent series of small textbooks is this recent number on glycosuria. No pretense is made of presenting the subject in a strictly original manner, the object of the book being simply to give in a condensed form the main facts which are known concerning the various diseases that give rise to the symptom of sugar in the urine, leaving polemics to larger treatises. As the series is prepared for practising physicians, that part of the subject which concerns treatment has been given with special fullness.

This volume owes its appearance to a fortunate conjunction of circumstances, the possession of sufficient funds for its publication by the Volta Bureau and the fact that the author was able to arrange a special investigation in connection with his official position on the staff of the Eleventh Census. The number of marriages thus collected is sufficiently great to render conclusions drawn from them of value. A difficulty which was met with at the outset was to accurately separate those congenitally deaf and those in whom the condition was the result of disease during infancy. It is often impossible to decide absolutely, but a judgment can often be formed from the probability that the congenital cases will have some history of ancestral deafness. In general the discussion of the results show that among the children of deaf parents deafness is quite frequent, the proportion being as high as eight per cent., and that the percentage is higher in children born of congenitally deaf than of those born of adventitiously deaf parents. Many other points are entered into and carefully studied, but it is impossible to abstract them here. The volume is certainly a most valuable contribution to our knowledge of this interesting and important subject.

BOOKS, ETC., RECEIVED.

An Introduction to Dermatology. By Norman Walker, M.D., Assistant Physician for Diseases of the Skin to the Royal Edinburgh Infirmary, etc. With a Frontispiece, Twenty-nine Plates, and Thirty-four Illustrations in the Text. Bristol: John Wright & Co.

Cerebellar Tumor or Masturbation?—Richard C. Cabot (Journal of the American Medical Association, May 13th; Medical Age, June 10th) reports a case of a boy aged fifteen who had had attacks of retraction of the head with some arching of the back, accompanied by headaches, increasing mental dullness, etc. He remained a week in the Massachusetts General Hospital, and the chief symptoms observed were headaches, unexpected vomiting, staggering gait, occasional involuntary passage of urine, retraction of the head, exaggerated reflexes, etc., these observations leading to a provisional diagnosis of cerebellar tumor, probably solitary tubercle. Nearly five years later he walked into the doctor's office the picture of health, when he incidentally remarked: "One thing I ought to have told you folks down to the hospital, but I didn't. I used to abuse myself a lot. After I went out of the hospital I left it off, and just as soon as I did I began to get better. Now I am all right, except I still stagger in the dark and my eyes are not first rate." March 24, 1899, he reported as perfectly well and hard at work.

The query is raised as to whether all the symptoms could possibly have been due to masturbation, or whether
Idiosyncrasy to Eggs: Poisonous Effects.—The Medical Age for June 23rd quotes a correspondent to the British Medical Journal for March 11th as follows: “A healthy young lady has symptoms of acute poisoning whenever she takes eggs in any form and in the minutest quantity, the severity of the attack being in proportion to the amount taken. Almost immediately she has rigors and vomiting; in a very short time the tongue becomes parched and dry, the throat sore, and there is severe headache and pain in the back. The very smallest quantity of egg, no matter how disguised in any other form of food, will produce symptoms more or less severe. They may continue from a few hours to two days. A tiny particle of the white placed on the skin produces nettle rash.” [We have personally known a very similar case.—Ed. N. Y. M. J.]

Strawberries and Gout.—The Lancet for June 24th cites a writer in Nature who speaks of the cruel medical tyranny which banishes the strawberry from the diet of the gouty and quotes what Linnaeus had to say about the curative properties of this delightful fruit. This great naturalist was persuaded to take strawberries during a severe attack of sciatia with the result that a sweet sleep ensued, and when he awoke the pain had sensibly subsided. On the next day he ate as many strawberries as possible, and on the following morning the pain was gone and he was able to leave his bed. Gouty pains returned at the same date in the next year, but they were dispersed as soon as Linnaeus was able to get strawberries. Although strawberries are forbidden to the gouty by some authorities, by others they are permitted, the fruit being regarded as a useful food for gouty persons on account of its richness in the salts of potash, soda, and lime, and its cooling diuretic and laxative qualities. The analysis of the strawberry shows it to be particularly rich in sodium salts, and in spite of the high percentage of water this fruit excels all other common fruit in the amount of mineral salts. The chemistry of the strawberry therefore would teach that this fruit is likely to be beneficial in gouty states.

Treatment of Ozena by Citric Acid.—Hamm (Münchener medicinische Wochenschrift, No. 15, 1899; Therapist, June 15th) states that first of all citric acid, like all fruit juices, acts as a powerful deodorizer, and completely removes the specific ozonic factor. Secondly, it possesses marked healing properties. The author obtained a cure in several cases. The mode of employment is as follows: Every morning the nose should be rinsed out and freed from pus and crusts. Then, by means of an insufflator, powdered citric acid is introduced three times a day, mixed with equal parts of sugar of milk. Deodorization can be noticed at once, and lasts for several days, even if the process is not repeated. The secretion is also speedily considerably reduced.

Convincing Evidence of the Value of Vaccination.—From the British Medical Journal for July 1st we learn that at a recent meeting of the Peterborough Board of Guardians, Mr. J. H. Howard, in the course of his report of a visit paid by Major T. Davey and himself to the Three Counties Asylum, announced his conversion to a belief in compulsory vaccination. They had, he said, found everything very satisfactory at the asylum—the most modern sanitary methods and appliances, an excellent water supply, and every arrangement calculated to insure the well-being of the patients. Notwithstanding this, small-pox had suddenly appeared, and attacked about forty of the inmates. Mr. Howard, hoping to find some support for his objections to compulsion, had questioned the medical officers on the subject of the outbreak, and was told in reply that in stamping out the disease they had relied simply on revaccination. With the solitary exception of one individual, every patient, every nurse, every doctor, every servant all through the house was revaccinated. The exception was a nurse—a fine healthy young woman—and the exception proved the rule, for she was attacked by small-pox and died of it. Such was Mr. Howard’s narrative to the Peterborough Guardians. Similar experiences, says the Journal, are common in small-pox epidemics, and he could easily have made himself acquainted with them through the reports of the Royal Commission on Vaccination and other reliable sources; but, after all, there is no schoolmaster like small-pox, and the nearer a man is to such a teacher and to such facts the more likely is he to be impressed by them, so that Mr. Howard’s conversion is not at all surprising in the circumstances which he related.

The Mississippi Valley Medical Association.—We learn from the Medical Bulletin for July that the annual meeting of this association at Chicago is to take place from October 3d to 6th, and not from September 12th to 15th, as originally fixed.

The Orleans Parish (Louisiana) Medical Society.—At the meeting of July 8th Dr. Isadore Dyer reported a series of cases of linear nevus, and demonstrated the evident relationship with a neurotic origin. Several photographs of various types of this variety of nevus were shown, from the simple pigmented to the highly vascular and verrucose types. Dr. Dyer related three instances of bilateral linear nevus, thus doing away with the proverbial nomenclature usually adopted of nevus unius lateris. He credited Dr. Prince A. Morrow, of New York, with establishing the more appropriate term of linear nevus.

Beer in Tablets.—“There is nothing very surprising,” says the Indian Medical Gazette for June, “about the statement that in a short time beer will be on sale in the form of tablets. In Germany the beverage has been reduced to a powder by a process of evaporation, and a very small quantity of the powder is needed, with the addition of water and carbonic-acid gas, to make a foaming tankard of ale just as good as if it were freshly drawn from the barrel. As the Manchester Evening News suggests, it is just possible that this new departure may ultimately have very important effects on the brewing and bottling trades, inasmuch as it will no longer be necessary to transport barrels and bottles. Solid beer yields another example of the strangeness of truth as compared with fiction. An Arctic explorer used to be fond of telling how, up in the far north, the ship’s beer froze and how it was necessary to break it up with crowbars, and then suck the pieces.”

The Insanity Problem.—Dr. H. E. Allison, medical superintendent of the Matteawan State Hospital, at Fishkill Landing, N. Y., writes that he has read with interest our recent editorial with this title, and he has been kind enough to send us two pamphlets of hi-
entitled respectively Provision for the Criminal Insane and Insanity and Homicide, one on The Criminal Insane in the United States and in Foreign Countries, by the Hon. Samuel J. Barrows, commissioner for the United States on the International Prison Commission, and the report of a committee of the American Medico-psychological Association on improvement in the medical service of prisons, of which he was a member. Dr. Allison remarks that the State of New York contains the oldest and largest institution for the custody of the criminal insane, and that the Matteawan State Hospital is now largely overcrowded, containing seven hundred and twenty inmates. Provision, he adds, is being made for this overflow by the erection at Dannemora of a special hospital to care for the insane who have been convicted of a felony, thus relieving the hospital at Matteawan and enabling it to provide for the unconvicted criminal cases from the courts and for the dangerous element, whose presence would be detrimental to the welfare of the inmates of an ordinary hospital for the insane.

Dr. Rose’s Article on the Term Appendicitis and Other Unscientific Words of our Nomenclature, which appeared in our issue for May 20th, has, we are informed, been published in Greek in Σαλτογε, a journal of the Island of Cyprus.

Hospitals as a Hunting Ground for Quacks.—We learn from the Sun for July 17th that a well-dressed man with an engaging manner, who left a circular behind him signed P. J. Dervin, 285 Bowery, got into Bellevue Hospital as a visitor on Sunday afternoon, the 16th inst., and began to peddle boxes of ointment which, he said, would cure almost anything if used with prayer. As soon as the hospital officials learned what the man was doing they started to hunt him up, but failed to find him. They found five boxes of his ointment, which looked much like tar, however, and learned that five patients had paid him fifty cents each before he left.

A Patient’s Device for Paralytic Incontinence of Urine.—The Edinburgh Medical Journal for July, quoting the Annals of Surgery for May, states that Dr. Otto Kiliani recently related to the Surgical Society of New York the case of a patient who at the age of twenty-nine years sustained an injury to the spine, attended with complete paralysis of the lower extremities, the rectum, and bladder. The legs improved sufficiently for him to walk about; he regained control of the rectum, but suffered greatly from incontinence of urine. He wore a portable rubber urinal for ten years. As this proved unsatisfactory, he discarded it in favor of an ordinary carpenter’s screw nail (an inch and a half in length), which he screwed into the orifice of the prepuce, the latter being quite insensitive. He came under the author’s observation for perforating ulcer of the foot after he had used the screw for six years. The margin of the prepuce was hard, thick, and almost cartilaginous, without the slightest evidence of ulceration. The orifice had contracted to a small opening, which, throughout its entire length (three quarters of an inch), bears a thread corresponding exactly to the thread of the screw, so that it only admits the latter when properly started. The sac of the prepuce has become dilated, so that it has a capacity of two hundred cubic centimetres, and the screw fits so exactly that it keeps the patient dry up to the pressure of this amount of urine, the prepuce, therefore, acting as a urinal or a secondary bladder. Dr. Kiliani had an ivory screw made to replace the steel one; the latter was exhibited to the members of the society.

By Another Mother.—The Medical Bulletin for July credits the following story to the Southern California Practitioner:

“Dr. H. G. Brainard and Dr. J. H. Davison composéd an insane commission recently before Judge York. The man before the court claimed in the early part of the examination that he was Napoleon Bonaparte, but later in the examination he asserted that he was the Duke of Wellington.

‘Ah,’ said one of the examiners, ‘how does it happen, a few minutes ago you said you were Napoleon and now you say you are Wellington?’

‘Oh,’ said the insane man cheerfully, ‘that was by another mother.’”

The Essential Qualities of the Nurse versus High-flown Language.—Dr. George M. Gould (Bulletin of Johns Hopkins Hospital for June), in an address to the graduating class of the Johns Hopkins School for Nurses, says: “‘Servants of the poor’ is another term used by orators to graduating nurses and by writers of mock heroics. It is quite highfalutin—and quite silly! I trust you will not go to your livelihood a victim of any phrase-maker’s tricks. Your first duty, like that of all of us, is to see facts; your second, is to know facts; your third, is to make facts. If you must durb yourself with any other titles and think of yourself as anything less or more than a nurse—quite a noble and ennobling name, I think—is not the word friend enough? A servant you must not be, a patronized or a patronizer you dare not be. Friendship is what is needed by the patient and by his family. The friend may teach and help, not serve or patronize; he must always sympathize with and love.”

Yellow Fever at Santiago.—Yellow fever is said to be very widely prevalent at Santiago. Among its victims was Major Clendennin, assistant surgeon in the United States army, whose daughter has recently recovered from the disease under treatment by Dr. Doty’s serum.

Il-assorted Marriages of Hermaphrodites.—Neugebauer (Centralblatt für Gynäkologie, May 6th; Medical News, July 15th) has collected reports of no less than fifty cases in which divorce has been granted on account of an error in the sex of one of the contracting parties. It seems incredible that such a mistake should occur so often, but the confusion of the genitals of some of these hermaphrodites was such as to deceive medical men who could not in some instances agree upon the sex of the individual, even after an examination. One remarkable case is recorded in which a male hermaphrodite had successively three husbands, and it was only after she, or rather he, had given a venereal disease to the third husband that the latter applied for a divorce. In forty-six out of the fifty recorded cases a man had married a male hermaphrodite. In one case the sex of the parties is not given, and in three instances women married female hermaphrodites. In one of these instances the supposed husband later became pregnant, and was delivered of a full-term child. There are numerous instances in which a matrimonial engagement has been broken on account of the discovery that the parties to the agreement were of the same sex.
CEREBRAL ABSCESS
IN A CHILD THREE MONTHS OLD,
COMPLICATED BY Erysipelas OF THE HEAD AND FACE.

Original Communications.

OPERATION. RECOVERY.

SYMPTOMS.

By WILLIAM J. DOYLE, M.D.,

PHILADELPHIA.

MAY 21, 1899.-Mother reported child unimproved. Oil not retained, slight vomiting, child very restless, got no sleep during the previous night, and but little during the day.

2nd.-Was asked to call and see the child in haste, as mother had discovered a large swelling on top of the child's head during the night. Found the child very cross, apparently suffering great pain; bowels had moved quite freely, but the movements were still green; pupils contracted; skin hot and dry. Temperature, 104° F. At the anterior fontanelle there was a pronounced swelling extending half an inch beyond its borders and elevated somewhat above the surrounding tissues. This elevation fluctuated slightly but distinctly upon pressure and was of an erythematous cast. Aside from the decided fluctuation there was absolutely nothing to direct attention to the probability of abscess. I am perfectly familiar with the child, having been present at its birth. It has never been sick; has no ear trouble or any remote probable cause, and no syphilitic taint; is plump and hearty in all respects, and has never got anything but breast milk.

Ordered two grains of acetanilide to reduce the temperature. Invited Dr. H. B. Nightingale to see the case, who, after an examination within the next three hours, fully concurred in my view, and we decided to operate at once.

An incision an inch in length was made in the scalp, extending antero-posteriorly and about a quarter of an inch to the right of the median line. The scalp was quite firm and thickened. Upon puncturing the dura it also was tough and resisting; cutting forward for about half an inch, all was well. Still cutting guardedly, I was surprised to find I had penetrated the longitudinal sinus, as announced by a profuse flow of venous blood. This haemorrhage was so profuse and persistent that the wound had to be packed to check it and the operation postponed. The dressing was removed forty-eight hours later. Haemorrhage had apparently ceased almost immediately; no pus, neither had any appeared the day previous. Wound lightly packed with gauze. Child had rested comparatively well during the night. Temperature, 191° F. No vomiting; bowels open but movements still green.

On the following day, upon removing the packing, it was found saturated with a greenish, foul discharge which welled up from the bottom of the wound—in all, about three fluid drachms or half a fluid ounce. Wound washed with solution of bichloride of mercury (1 to 5,000). Repacked lightly in expectation of its sufficiently draining without further interference. The temperature had fallen to 99° F. Next day there was practically no discharge, nor has there been any since, and the child is making an uneventful recovery.

Now, as to erysipelas. It developed distinctly, but not markedly, both on the head and in the face, following the usual course of mild attacks, and the child today is practically well. What was the cause of this deposit, and where was it located?

Cerebral abscess is a focal supplicative process affecting either the white or gray matter, or both. It may be single or offer numerous points of suppuration. The symptoms may be acute, developing within a few hours, or, coming on insidiously, may consume weeks or even months before becoming of diagnostic value.

Clinically, the symptoms of cerebral abscess may be divided into general and local: general symptoms pointing to pressure or irritation, while local symptoms indicate perversion of function, being modified by the seat of the abscess.

The commonest general symptoms are, perhaps, headache, lassitude, disturbance of sleep, perversion of intelligence, vertigo, convulsions, and optic neuritis; while the temperature is either normal or but slightly elevated, and may even be subnormal.

With an abrupt rise of temperature, the case presents a picture decidedly suggestive of an acute meningitis, and it is exceedingly difficult to make a distinction at this stage, especially if general convulsive seizures are added.

In cases developing gradually, the symptoms are generally less pronounced; headache may be but slightly marked and not persistent, vertigo and vomiting may be entirely absent or occur at intervals only. Instead of coma and somnolence there may be simple apathy, mental confusion, and irritability. After a shorter or longer time, however, the disease is sure to assert itself, and evidence of specific disturbance will be observed, by which the location of the abscess will be determined.

The location of an abscess of the brain is largely determined by its cause. When due to extension from disease of the ear, it will be found generally in the

Mary P., aged three months, abscess of brain; operation. Recovery.
temporo-sphenoidal lobes, the cerebellum, or the region of the pons. If the pus is the result of a phlebitis of the lateral sinus, the abscess will in all probability be found in the cerebellum. If it enters through the superior petrosal sinus, the abscess will be found in the cerebrum, and in all likelihood in the temporal lobe. When caused by external violence, the deposit usually bears some relation to the site of injury, but not invariably, as shown by abscess of the occipital lobe caused by injury to the frontal region. When due to necrosis or disease of the facial bones, the abscess is frequently located in the frontal lobes or at the base. When due to syphilis or tuberculosis, its site is usually the motor convexity, base, or cerebellum. Pyemia is prone to induce multiple abscesses, generally in the regions about the distributions of the middle cerebral artery.

The principles of localization of uncomplicated abscess situated in an active region apply with marked constancy, the circle of symptoms indicating quite regularly the point of pressure. However, cases have been reported where the abscess was only discovered after death, there being absolutely no indications during life of any brain disease.

Ordinarily, in patients suffering from cerebral abscess, it is quite evident that some brain affection exists, but it is not by any means an easy matter to decide from the symptoms that abscess is the trouble. Tumor, meningitis, and sinus phlebitis are apt to present claims for consideration, and these claims are the more important inasmuch as the same causes obtain in the production of meningitis and of sinus phlebitis; neither is the temperature always a reliable guide, for, while usually above normal and sometimes quite high in meningitis and phlebitis, it may also follow the same lines in abscess, though as a rule it is nearly normal, but may be quite irregular. In meningitis the onset is most marked; excitement and delirium are conspicuous features; intolerance of light, a tendency to general convulsions, and a general hyperesthetic condition develops. It is only in meningitis of the base that pronounced focal symptoms appear, and then are dependent upon the number and extent of implications of special nerves. If the inflammatory process is thus localized it is almost impossible to distinguish between it and abscess.

Abscess of the brain is invariably dependent upon the introduction of micro-organisms from near-by or remote sources, and occurs at all ages, most frequently during adolescence or early adult life. It is exceedingly rare in infancy and old age, while its most frequent cause is extension from middle-ear disease, and from chronic rather than from acute troubles, the next most common cause being traumatic injuries of skull and face. In infants, practically all reported cases have been due to the latter causes. Pus accumulations, however remote, may be a means of brain infection through the circulation.

The development of such abscess is steadily progress-

ive, except when, as at times occurs, it is encapsulated, when it may remain for quite a long time quiescent; however, there is the ever present danger of rupture, such rupture simulating apoplectic symptoms, resulting generally in death.

Unless treated surgically, abscess of the brain is almost inevitably fatal. Its duration is variable, acute cases generally ending within a week or ten days. The encapsulated form may extend over years, the patient eventually dying from exhaustion, or quite unexpectedly from rupture of the encapsulating membrane.

The method of treatment can only be by surgical procedures, and in no department of medicine have the results accomplished been more brilliant or promising than in the surgical treatment of brain abscesses. The surgeon should not wait for coma or grave symptoms, but should open the cranial cavity as soon as the symptoms point to the formation of abscess.

1627 Ritner Street.

MODERN THERAPY OF THE TYMPANIC CAVITY.*

By M. A. GOLDSTEIN, M. D.

Professor of Otology, Beaumont Hospital Medical College; Consulting Aaurist to the Alexian Brothers' Hospital, and to the Sisters of St. Joseph School for the Deaf; Associate and Laryngologist to the Terminal Railroad Association; Vice-President of the Western Ophthalmological and Oto-Laryngological Association.

In the progress of otology, like that of other special departments in medicine, there is a tendency to "fadism," which has been especially marked during the past few years. A review of recent literature and a glance at the titles of papers read at otological meetings, both at home and abroad, indicates a steady increase in the consideration of the mastoid operation in its varied forms, and of the radical operative procedures for the relief of chronic supplicative conditions of the tympanic cavity. Mastoid and intratympanic work have become almost as prevalent in otology as an operation for appendicitis and the removal of the offending member in abdominal surgery.

It is true that in a series of well-selected cases mastoidotomy and ossiculectomy often afford brilliant results. With the operative fever tingling in his fingers, however, the otologist is inclined to overstep the mark from time to time, and institute radical measures where a more conservative treatment may be indicated, and the results obtained be equally satisfactory.

I would leave out of consideration that large series of cases of acute middle-ear complications where bacteriological inroads are rapid, and where the indications for radical measures are definitely pointed out. It is to that large class of cases of chronic supplicative conditions of the tympanic cavity where the constant presence of

* Read at the fourth annual meeting of the Western Ophthalmological and Oto-laryngological Association, New Orleans, February 10, 1899.
purulent secretions threatens the destruction of the soft tissues of the tympanum, where ossicular necrosis is imminent, and where an extension of the inflammatory products to the accessory spaces of this cavity is possible. It is here that the radical otologist, with his often too active interference, frequently promotes unfavorable results.

A question which has often been of considerable bacteriological interest to me is the fact that micro-organisms can be harbored within the confines of the middle ear cavity for so long a time without giving rise to a further extension of the inflammatory process. It is of almost daily occurrence in the work of the otologist to come in contact with suppurations of the middle ear which have existed for months and years without much indication of tissue destruction and without causing the patient any inconvenience beyond that of discharge. This fact should appeal to us as one of much clinical value. Here is a cavity lined with mucous membrane which, microscopically, is almost identical in structure with that of the Eustachian tube and its nasopharyngeal orifice. Not only does this continuity of tissue extend from the nasopharynx to the tympanic cavity, but the attic, the antrum, and the mastoid cells are similarly lined with mucous membrane. Considered from a bacteriological standpoint, we know that micro-organisms find an especially favorable habitat on mucous membrane, and that this suitable culture medium, supplemented by the moist serous surface of the mucous membrane and a fairly uniform temperature, offers the best possible opportunity for the rapid spread from an infected focus.

We know furthermore that over seventy per cent. of the suppurative affections of the tympanic cavity are due to an extension and infection from the nasopharynx via the Eustachian tube. Through this section of the mucous tract an extension to the tympanic cavity is rapid; conversely, in the chronic forms of suppurative infection of the middle ear an extension to the more vital areas of the attic, antrum, and mastoid is slow. It would be interesting to determine the reason for this decided difference in the tendency of micro-organisms to spread; on the one hand, the rapid spread from the nasopharynx via the Eustachian tube to the tympanic cavity; on the other, the slow progress from the tympanic cavity via the attic and antrum to the mastoid cells.

Supported by these bacteriological and clinical facts I maintain that more conservative procedures are conducive to the best interests of the patient, are more rational, and offer fewer possibilities as to unfavorable results.

I do not assume that even the most radical enthusiast will undertake operative measures for the relief of chronic suppurative otitis media until he has given a fair trial to milder measures. It is to the application of these therapeutic measures that I desire to direct your attention.

In a brief paper recently published I attempted to compare the two systems of treatment which have in recent years been given every practical test—one, the so-called "dry treatment," the other, the irrigation and syringing with various antiseptic solutions. In summing up the advantages and disadvantages which either of these methods might afford, I have considered the pathological status of the affected area, the character of the discharge, and the size of the perforation as factors.

From a close comparison of these two methods I believe that frequent use of the syringe and lavage of the auditory canal are distinctly contraindicated in suppurative cases where large perforations of the membrana tympani exist, and where a free entrance of the fluid into the tympanic cavity is so easily effected. In the first place the mucous membrane of the tympanic cavity, bathed in purulent secretions, affords an excellent supply of infectious material, which the force of the current from the syringe or douche may wash into the remote and healthy areas of this cavity, and may thus mechanically produce an infection of the attic or antrum where none had previously existed. I think I can substantiate the assumption that many of the cases requiring mastoid interference or ossiculectomy have been unconsciously produced by the too liberal use of the syringe in the cleansing of the tympanic cavity.

Otological literature contains frequent references and admonitions as to the indiscriminate use of the nasal douche, especially when handled by the patient himself, and points to a subsequent infection of the tympanic cavity as the result of this procedure. If this is so frequently possible by the carrying of the fluid through the entire tract of the Eustachian tube, how much more readily can a similar result ensue when the syringe is brought directly into contact with the tympanic cavity through a large perforation of the membrana tympani.

The second factor contraindicating the use of aqueous fluids in these conditions is the pathological status of the tympanic cavity itself. The mucous membrane of the tympanic cavity during a suppurative otitis is constantly bathed by purulent secretions, resulting in a sodden, boggy surface, and this is accentuated by the addition of aqueous fluids. It is this very stimulation and irritation of the mucous membrane by the fluids with which it is brought into contact that causes granulation and polypus formation. It should be our object to extract fluid from this area and not to add to the already existing serous or purulent infiltration.

Where the discharge is viscid, tenacious, and copious, the application of the syringe with a gentle current of a mild, warm antiseptic fluid may be advocated to clear the auditory canal to the surface of the membrana tympani. Beyond this point, however, it is my opinion that the syringe should not be used in suppurating conditions of the tympanic cavity.

* Laryngoscope, December, 1898.
Clearing the auditory canal of these copious discharges may be just as readily accomplished by the use of strong solutions of peroxide of hydrogen, such as hydrozone or the full-strength $\text{H}_2\text{O}_2$ of the Oakland Chemical Company. This obviates the necessity of the syringe and the considerable pressure of the current of the fluid which is often necessary to dislodge these rpy purulent shreds.

I am also opposed to the use of the middle-ear syringe in any affections of the tympanum other than in mild cholesteatoma. Here we deal with a moderately dry cavity, and an alkaline antiseptic solution used with a middle-ear syringe is frequently effective in detaching these epithelial masses.

The technics in surgery which has found general favor of late is the "dry dressing." Its advocates and enthusiasts claim for it a more rapid healing, a more natural covering, less irritation of the injured surface, and less danger from infection of the surrounding areas. The "wet treatment" always produces an infiltrated surface, and as this in the ear is generally applied to the mucous membrane, it unintentionally aggravates that condition of "bogginess" which it is our purpose to subdue.

For clearing the auditory canal of pus or muco-purulent discharges, I have found a small tuft of sterilized cotton wound about the end of a probe or cotton carrier, frequently renewed, and gently applied as a mop, a more effective cleansing agent than a large current of antiseptic fluid.

If but a small perforation exists and the cotton tuft can not find its way through this perforation into the tympanic cavity, there is always a possibility of retention of the purulent matter and a tendency to prolonged suppuration. In suppurative otitis media of a chronic character, where no pain or discomfort exists, I employ the Eustachian catheter in connection with a nebulizing or vaporizing apparatus, thus accomplishing the three-fold result of inflating the middle-ear cavity, of clearing the tympanum of pus and forcing it by a medicated compressed-air current through the perforation, and of medicating the middle-ear cavity more effectually and with less unfavorable possibilities than by the use of an aqueous fluid. My nebulized fluid consists of iodine, three grains; carbolic acid, four grains; and benzoil or albolene, one ounce. This I use in conjunction with a Globe hand nebulizer, the supply tube of which is fitted with a special tip, which in turn is snugly adjusted to the proximal end of the Eustachian catheter. In this way my medicated vapor is insured a thorough penetration of the tympanic cavity, and the inflation may be continued ad libitum. The simplest index for determining the volume of vapor which reaches the middle-ear cavity in this manner is to watch the vapor as it passes out of the auditory canal. I have frequently succeeded by this steady inflation, continued for five minutes at a time, in forcing the residue of the purulent matter through small perforations of the membrana tympani in a single sit-
fullness in the ear. The syringe is then detached and the cone-shaped tip of the compressed-air apparatus applied; a few short taps, and then a steady pressure continued for eight or ten seconds is given. This insures the penetration of the tympanic cavity by the fluid. I have convinced myself on numerous occasions of the penetrability of this fluid by applying it not only in chronic catarrhal conditions of the middle ear where the membrana tympani was intact, but also in the treatment of middle-ear cavities, suppurative or non-suppurative, where perforations of the drum membrane existed; where such perforations are present this dark-colored oily fluid may be found on examination exuding into the auditory canal.

It is understood, of course, that the auscultation tube is employed in these inflations: in the first place to determine the patency of the Eustachian tube; in the second place to recognize the bubbling sound which is made by the injected fluid as it enters the tympanic cavity.

The patency of the Eustachian tube is also a question which has not been neglected in this therapy and has offered no hindrance to this intratympanic medication. Where the examination of the patient has determined the fact that the Eustachian tube offers obstruction to the free passage of air or fluids, or where irregularities in the nasal passages occur to prevent satisfactory catheterization, I have made use of the following techniques, which may be considered radical, but not quite so extreme as an excision of portions of the membrana tympani or ossiculectomy:

This consists of intratympanic injections made by puncture of the membrana tympani under aseptic precautions and the introduction of the same formula as used through the Eustachian tube. For this purpose I have had an extra long and long hypodermic needle constructed and fitted to an ordinary hypodermic syringe. The shaft of the needle is bent at an angle of thirty degrees, is two inches and a half in length, so that it may easily reach the drum membrane. The end with which the puncture is made is supplied with a small flange an eighth of an inch from the point. This precaution has been adopted to prevent the needle from penetrating the tympanic cavity too far, or the possibility of injury to the delicate tissues by undue movement of the head of the patient. Partial cocaine anesthesia is effected by the retention of a cotton plug saturated with a hot ten per-cent. solution of cocaine. Three or four drops of the carbol-iodine solution are injected into the tympanic cavity. The reaction is slight, and the injection may be repeated in a week or ten days.

I have placed special faith in this method of treatment in its several forms, because the actual results have been better in my experience than those of the many various treatments that have been thus far tried.

Anatomically and pathologically we deal here with aural conditions analogous to those of the nose: hypertrophic rhinitis is to the nose what hypertrophic otitis is to the ear: atrophic rhinitis and ozena are to the nose what sclerotic otitis is to the ear. It is logical to conclude, therefore, that the system of treatment which yields favorable results in these pathological affections of the nose should be equally applicable to similar affections in the ear. The greatest difficulty to overcome is that of properly reaching the affected cavity, and this I think can be most effectively accomplished by the simple procedures here described.

I have made another departure from old beaten paths in middle-ear therapy. The saturated alcoholic solution of boric acid has been an old and trusty friend for the reduction of mild granulations in the middle-ear cavity resulting from the irritation of suppurative exudates. The dehydrating properties of alcohol and the antiseptic value of boric acid have been combined in an effective solution for the reduction of such tissue. In order to get the full dehydrating effect, absolute alcohol should be employed in this solution. It may not have occurred to you, however, that this solution brought into contact with such delicate sensitive tissue causes excruciating pain to the patient. I have found a satisfactory substitute in picric acid; this is of value both as a desiccator and as an antiseptic; it can be used with weak alcoholic solutions and thus avoid the intense pain caused the patient. It may be also used in combination with glycerin, whose dehydrating properties are almost equal to those of alcohol.

In the scope of this paper I also desire to offer a brief report on another form of treatment which has been suggested in chronic non-suppurative middle-ear affections. I refer to ferments employed to dissolve fibrinoplastic deposits and fibrous adhesions in the middle-ear cavity. This therapy was first described in detail by Cohen-Kysper, of Hamburg (Archives of Otology, vol. xii, No. 2). The author employed pepsin of the dog and injected the sterilized solution under antiseptic precautions (intratympanic) by perforating the membrana tympani with a large-sized hypodermic needle. I corresponded with the author for some time, but was unsuccessful in obtaining some of this specially prepared ferment for trial. As I was anxious to test the possibilities of this treatment I placed the matter of the preparation of such a ferment with Fairchild Brothers & Foster, whose long experience with pepsin products suggested a similar preparation. Through the courtesy of this firm, and with the assistance of their chemist, I obtained a supply of pepsin solution to which I have devoted some time and attention during the past six months, following the method advocated by Cohen-Kysper. The results obtained in a series of some twenty cases, especially selected for this purpose, did not encourage me in continuing these clinical tests. It is possible that stronger pepsin solutions, with some variations in their preparation, may yield better results.

Closely associated with the direct medication of the tympanic cavity is the therapy employed for the relief
of tinnitus aurium. Early in 1838 Robin and Mendel published the results of their various successful efforts with cimicifuga racemosa in the treatment of tinnitus aurium. During the past three months I have used this preparation liberally, and fail to understand why my results did not correspond with the favorable report of the authors. I have used the fluid extract of cimicifuga in graded doses ranging from ten to thirty drops. Exhibition of this drug certainly raises arterial tension, and subsequent vertigo, headache, nausea; and a feeling of fullness was complained of almost universally by my patients. A rough estimate of the results obtained by the use of cimicifuga in my experience would indicate that about five per cent. of the patients so treated were benefited. In nearly all the patients to whom cimicifuga was administered the tinnitus aurium was of recent occurrence. It is possible that much of the success of this drug depends on the use of a fresh and pure preparation and special care observed in its administration.

In presenting this series of therapeutic considerations I have not given the literature of the subject much detailed attention, and have simply expressed views that have occurred to me from time to time in my own work. Perhaps little of the information which may be gleaned from this paper is new. I may have been anticipated in the recording of these suggestions. The results of the plan of treatment above outlined have proved so satisfactory, however, that I have been prompted to present and to urge the necessity of giving such measures a fair and careful trial in the chronic cases to which they are adapted before resorting to more radical operative procedures.

3702 Olive Street.

**ANAESTHESIA:**
**NITROUS OXIDE; ETHER; CHLOROFORM.**

By S. ORMOND GOLDAN, M. D.

Preliminary Remarks.—I think all will agree that it is only by the extended observation of the practical administration of anæsthetics that one is enabled to acquire or lay claim to any special skill in their administration. Dangerous symptoms arising during narcosis are more frequently the results of the improper methods employed and of inexperience than of the anæsthetic, which is usually credited with them. Properly administered, the instances in which dangerous symptoms occur will be exceedingly rare; occasionally, however, even when taking every precaution, emergencies will arise necessitating immediate and appropriate treatment. Certain symptoms occur during the induction of anæsthesia which to the casual observer might call for attention; the experienced administrator recognizes these symptoms simply as the expression of the effects of the anæsthetic upon the system, and carries the patient safely on to complete anæsthesia; other symptoms, again, seem of small importance, whereas, in reality, their early recognition and removal will prevent dangerous symptoms and often collapse.

From the present state of knowledge we are unable to foretell in any individual case when dangerous symptoms will arise. It is for this reason that every patient who is anæsthetized is entitled to and should receive at the hands of the anæsthetist the benefit of every detail, as much so as does the operation itself at the hands of the surgeon. If every one who administered an anæsthetic realized that in doing so there was always an element of danger, and that to him alone belonged the responsibility for the life of the patient, he would not fail to provide himself with every possible means for the recognition and treatment of the symptoms which, if neglected, might be the cause of the patient's death.

To those who think anæsthesia of little importance, and consider attention to details superfluous, it may be said that sooner or later they will certainly come to grief.

It is well known that patients frequently dread the anæsthetic more than the operation, and this, I have conclusively proved, is more often due to the way the anæsthesia has been conducted than to the particular anæsthetic used. I can repeat, as I have elsewhere stated, that an ideal anæsthesia should not only have for its object immunity from death, but should be so conducted that the patient's return to consciousness should not to the slightest degree be marked by the knowledge of having undergone narcosis. This can not be perfectly accomplished with the anæsthetics now in use; but this desire is attainable more than is usually supposed in the majority of cases which I have demonstrated in patients who had at previous periods in their history been anæsthetized with crude methods, though the anæsthetic had been the same.

If, then, I am construed as giving unnecessary attention to details, I hope my plea for the importance of the subject will be accepted for so doing.

The essentials for a proper narcosis are:
1. One who does not look lightly upon the subject, for the anæsthesia is, in point of importance, second only to the operation itself.
2. A thorough knowledge of the effects of anæsthetics upon the human economy.
3. The recognition of untoward symptoms, which, if rightly interpreted and treated, will often prevent dangerous ones ensuing.
4. A thoroughly equipped armamentarium; this consists of the anæsthetic apparatus and every instrument and stimulant one is likely to use in any possible emergency.

The narcosis can be conveniently divided as follows:
1. The preliminary preparation of the patient.

---

* Read before the Medical Society of the County of New York, February, 1898.
2. The induction of the anaesthesia and its maintenance.

3. The subsequent treatment of the patient who has been anesthetized.

Anæsthetics used

Consciousness regained. Vomited. Nausea. Observations:

A complete history should be a part of every well-conducted narcosis. This is best arranged in a printed form in three parts: The patient's history; the narcosis; and post-anæsthetic observations. The reverse of the sheet is used for detailed notes of the anaesthesia, which will be found of great interest. Where the anæsthetist has no such blank, he should keep complete notes throughout the narcosis. The value of such a history is obvious. Hardly more than the mention of the anaesthetic used is ever noted in the majority of hospitals; the method employed and quantity of anaesthetic used are rarely if every stated. It often becomes necessary to anæsthetize the same patient twice or oftener. Here a history of the previous narcosis would be of great value. If any untoward symptoms occurred, the anaesthetic or method might be changed. We can by such a history in a systematic way note the effects of different anaesthetics and quantities used upon kidney, heart, and lung lesions in particular types of patients—those who require stimulants, etc. A glance at the history sheet will show its value. In private cases the anæsthetist rarely sees the patient before the time set for the operation; in this case he should ascertain and note what preparation the patient has had; the particular drugs used; whether the patient has had a physical examination, and whether he ever has been anæsthetized.

before. Inquiry should be made as to whether he has ever had acute cardiac or pulmonary disease; whether he has been addicted to the use of alcohol, morphine, cocaine, or any other drug habit. It is known that certain diseases leave their permanent impress upon the system, and in each individual case the anaesthetic can be so modified that untoward symptoms will not occur as the result of an early lesion. A general survey of the patient should be taken; his size, probable weight, temperament, color, and condition of the skin and mucous membranes observed; the state of the pupils; the temperature and pulse noted, and a thorough examination of the lungs, heart, and arteries made, for upon this examination often depends the selection of the anaesthetic. As to the kidneys, the urine should, of course, always be examined. The examination usually consists of the chemical test for albumin, and, if the so-called trace is found, it should not be taken as an indication for the selection of chloroform in preference to ether as the anaesthetic to be used. Whenever albumin appears, a microscopical examination should be made. It is well known that albumin may appear in the urine without any actual disease of the kidneys, and—directly the reverse—grave kidney lesions be present without albumin.

I do not believe the presence of albumin contraindicates ether, if it is properly given, and, everything considered, it is, in fact, in these cases as safe as chloroform. It is always wise in patients in whom albumin has been found before narcosis to examine the urine a few times after the anaesthesia. My practice is to make such an examination upon the first and second days following narcosis, and once after two, three, or four weeks, according to the nature of the operation. It is also of interest to examine the urine after protracted narcoses, even in those cases in which albumin has not appeared.

While various drugs may be used for catharsis, in my estimation a mercurial purge is the preferable one as a precedent to anaesthesia, and for this purpose the mild mercuric chloride may be employed, either in repeated small doses or in one large dose, always being succeeded by a saline, preferably the magnesium sulphate. Where calomel is used, it should be given at least two days before operation, and in some cases four days, for the reason that calomel is nauseating to some patients, and it is desirable to have this entirely cease before the day set for the operation. A mild saline aperient, however, may subsequently be administered the day preceding the anaesthesia. It is well known that calomel increases the flow of bile, and so counteracts intestinal fermentation; this, with a saline, will leave the intestinal canal in as good condition, both for anaesthesia and operation, as it is possible to do. This treatment will also greatly lessen the subsequent nausea and vomiting following the narcosis. It is desirable to have the patient in as good a physical condition as pos-
If stimulation is necessary, appropriate doses of the drugs desired (preferably strychnine or the tincture of nux vomica) should be administered days or weeks before the anæsthesia occurs, and not postponed until dangerous symptoms occur, and large doses of stimulants have to be relied upon to counteract their deleterious effects. All patients should be encouraged to drink an extra supply of water—a glassful at stated intervals during the day; or once daily the colonic saline enema may be given, preferably at midday, in the Sims or dorsal position, in which the patient should remain a short time, so that it may be retained. The quantity should be about two quarts. This is particularly valuable in septic cases; in those suffering from shock, in whom a long narcosis is probable, it maintains the vaso-motor tone, and also conduces to increased cardiac and respiratory activity; it causes a free secretion of urine, and consequently a rapid elimination of the anæsthetic. In this way we infuse the patient before operation, and often avoid the necessity for so doing during or following it. The food of a patient who is to be anæsthetized should be of the most sustaining—a liberal mixed diet up to the very day of the narcosis. The custom of giving liquid diet for days before operation, unless specially indicated, is not, in my judgment, good; but on the day of the operation only concentrated broths should be permitted, and no food whatever for at least five hours preceding anæsthesia. Gastric lavage should be employed in emergency cases, and a knowledge of how to quickly and properly introduce a stomach tube is essential. From eight to twelve ounces of water should be introduced at a time, and repeated until the water returns perfectly clear.

Narcotics, such as morphine and whisky, should, as a rule, **not** be given before anæsthesia; they are unnecessary, and in reality dangerous. It is interesting to note that those who advocate the practice are not in the habit of producing anæsthesia without the so-called prophylactics. The usual procedure is to give from a fourth to half a grain of morphine and from one seventy-fifth to one one-hundred-and-fiftieth of a grain of atropine, and sometimes, in addition, whisky in variable quantities. Whether the patient has ever had these narcotics before or has been addicted to their use is rarely inquired into; the consideration as to whether he is abnormally susceptible to the drugs in these particular instances seems to be forgotten.

The advantages alleged for the use of morphine are that less of the anæsthetic is required during the anæsthesia; the patient is anæsthetized more rapidly; excitement is greatly lessened, and it is a cardiac and respiratory stimulant. From very extended observations I am able to say that morphine does not in any way diminish the quantity of the anæsthetic used to induce and maintain anæsthesia, nor can anæsthesia with either ether or chloroform be induced more rapidly with morphine than without its use; if properly administered, the amount of the anæsthetic used and the time to induce the narcosis will in each case be less without morphine than with it—instead of lessening excitement it often increases it. As for its being a cardiac and respiratory stimulant, there is in strychnine a much better stimulant for this purpose; but morphine is a direct respiratory depressant, and accidents referable to respiration have occasionally occurred which could very properly be attributed to its use. It also interferes with the motility of the iris, and this function during anæsthesia should never be impaired. It is true that morphine deepens narcosis, and for that reason should not be used. How the degree of anæsthesia can be determined with any certainty when morphine has been used I can not understand. I have further observed that patients who have had morphine before anæsthesia have more nausea and vomiting than those who have not had it. Morphine, however, is valuable after the operation and when the patient has regained consciousness. We thus avoid the opium narcosis being superimposed upon that of the anæsthetic. Here, from the nature of the operation, and if the operators desire it, it may be given preferably in quarter-grain doses with an appropriate dose of atropine; it should not be given in frequent small doses. Whisky should be avoided, as it increases excitement and deepens narcosis at the same time; an empty stomach conduces to a good and rapid anæsthesia.

Strychnine is certainly a superb stimulant, and there is really no theoretical or practical objection to its use; however, the custom of certain English anæsthetists of using as much as a third to half a grain is unnecessary and not devoid of danger; and it is far more rational, it seems to me, to give the drug, when necessary, at the beginning of the narcosis in a thirtieth- to a twentith-grain doses and at intervals repeat it during the anæsthesia. In this way we have a gradual and constant stimulation and do not at once introduce into the circulation a quantity which can possibly cause tetanic spasms of the respiratory muscles, which, with the anæsthetic, can easily lead to asphyxia.

The patient should be warmly clad, and the garments so arranged that they can be easily removed, if necessary, after the operation. The patient should, if possible, remain in bed for twenty-four hours before the narcosis; artificial teeth should, of course, be removed before the inhalation begins, and under no circumstances should they be replaced until the patient has fully regained consciousness; to avoid being misled, the mouth should be examined after the patient is anæsthetized.

The temperature of the operating room should be from 80° to 85° F., and the patient should be kept covered with woolen blankets throughout the narcosis, special care being observed when, for any reason, the patient is moved from one room to another. The temperature falls during the administration of anæsthetics;
this is not only due to the increased loss of bodily heat from the anesthesia, but largely to a decrease in tissue metabolism. I have seen the temperature fall eight degrees in a septic case in which, before beginning the inhalation, the thermometer registered 103° F. (the patient had had a continuously high fever), and at the end of the first half hour of anesthesia the temperature had fallen to 95° F. The anesthesia can be begun either with the patient in bed or in an adjoining room to that in which the operation is to take place; or, if he is not nervous or easily frightened at the operative preparations, it may preferably take place in the operating room itself.

The posture of the patient is preferably the dorsal one, but any posture may be used, according to the nature of the operation, such as the prone, the side, or Sims's posture. Here particular care must be taken of the patient's arms and legs, that subsequent paralyses will not result. The crutch or apparatus for maintaining the posture of the patient also needs attention, that pressure may not occur on supplying nerves. If the Trendelenburg posture is necessary, from time to time the patient should be returned to the horizontal, and so avoid the continual stress upon the diaphragm. When nitrous oxide is used, the sitting or recumbent posture may be used. Some English anaesthetists also give ether in the sitting posture. It must be said, however, that chloroform must never, under any circumstances, be given in any but the recumbent posture, as it is a circulatory depressant, tending to cause vasomotor paralysis, which the horizontal posture tends to counteract. Deaths have occurred when taking chloroform in the sitting posture for the extraction of teeth.

The more proficient one becomes in the administration of anaesthetics, the less frequently will arise emergencies, the means for treating which should always be at hand, and may consist of the following:

Proper ether inhalers.
Chloroform inhalers.
Ether, in small quantities in hermetically sealed containers.
Chloroform, in tightly corked bottles.
Chloroform drop bottles, preferably the kind made with the ground grooved-glass cork, by which the anaesthetic can be made to flow drop by drop, with the required rapidity.
Alcohol, in a glass-stoppered bottle.
A glass funnel and graduate.
A Mauders's screw gag for opening the mouth.
A Denhardt's or Mason's mouth gag protected with rubber.
Tongue forceps; for this purpose a Liére's serre-fine or the broad Péan haemostatic forceps, or Hunter's sponge forceps may be used.
Sponge holders.
Tracheotomy instruments.
A Hagedorn needle threaded with strong silk.

Four to six feet of rubber tubing.
Soft-rubber catheters of three sizes.
The canalized Wales bungs.
Several hypodermic syringes.
Hypodermic needles in a glass receptacle.
Several pieces of gauze, of the size required for ether and chloroform inhalers (sponges should not be used).

A glass-stoppered bottle filled with boric-acid solution, for use in dissolving hypodermic tablets.
Hypodermic tablets of strychnine, atropine, morphine, digitalin, caffeine, etc., single or combined in various ways.

Then the nitrous-acid inhaling apparatus. This is all carried compactly in a leather satchel.

It is interesting to note that the first three anaesthetics used in surgery are still at the present day in the highest repute. We can with advantage discuss them in the order of their acknowledged safety.

In the selection of the anaesthetic to be used we must consider:

1. The character of the operation.
2. The particular type of patient.
3. Results of the patient's physical examination.

(To be concluded.)

ODD TYPES OF DISEASE.*

By F. SAVARY PEARCE, M.D.,
PHILADELPHIA,
INSTRUCTOR IN PHYSICAL DIAGNOSIS IN THE UNIVERSITY OF PENNSYLVANIA; CHIEF OF THE MEDICAL CLINIC, ST. AGNES HOSPITAL.

That the routine outlining of diseases as quite exact entities is the ideal and desirable method of teaching can not be gainsaid. Such diagrammatic instruction presents the cardinal points in tangible form. But that there are a certain percentage of truant affections, especially in the nervous system, is to be emphasized. Here it is that lesions may happen to be in a part of comparatively small importance; or it may be that the same disease process is existent in a more vital situation, or in some closely contiguous structure, so that localizing symptoms will be exact. Here timely treatment may cure or aid in prevention of further trouble. Or, again, an aberrant symptomatology may result from a lesion affecting the system of nerve fibres or of their central neurones; then the semeiology may far exceed the anatomico-physiological pathogenesis, especially if function is lowered from other intrinsic causes. Finally, and somewhat the converse of the foregoing, the most difficult cases are those where there is an apparent compatibility of normal function with abnormal structure—i.e., where vicarious action maintains the balance until the "breaking strain" of some extrinsic cause is "the last straw," and a sudden degeneration ensues.

* Read before the Academy of Medicine of Atlantic City, N. J., April 14, 1899.
Hence, the physiological disturbance possible following upon an initial or insidious lesion in a definite neuro-anatomical site may soon become so widespread or erratic in the symptom production following the secondary phenomena thus set up, that the best observer may rarely have to acknowledge defeat with all his modern methods. When the chain is once broken morbid physiology may also run riot and the usual symptoms not present. It occasionally happens, therefore, that the accurate dividing line, even between one so-called system disease of the cord and another, is not infrequently indeterminable early, just at the time when most good could be done by therapeutics. Or the dominant symptoms of these nicely defined tract affections later may be readily discerned, or, still more advanced, again confused, where in both medicine can do least for the sumnum bonum of the afflicted. So in the transition from minor to major, observation of many cases will have been paramount ere you honor a topographical or nosological diagnosis in these exceptional diseases—the odd types. Many of the passing neural symptoms casually seen in general affections must be critically studied in the future for proper interpretation of etiology, and hence of rational treatment, before the severer organic lesion is set up. The ideal is to seek pathogenesis more than pathology.

The statement made by some wise author, in purport, that all ships look more romantic than that upon which we sail, bears a close analogy to the difficulty in accurately diagnosticating some of our own cases, where the paradox of the palesene seeming to be the real luna of signs is most confounding. The study of the individual case most thoroughly, then, will make early diagnosis, and hence therapeutics, brighter.

It is for all these reasons that I drop routine tonight and take up some classes of cases that can bear especial study in order to make out those rarer peculiar morbid entities, points which come by intuition, some may declare; but is this not an expression of a critical though quick observation of details?

Cord Diseases.—Tabes dorsalis* has been reported by the writer, with an analysis of one hundred and ninety-four cases, especially with reference to the oddity of precocious cases, in that the Argyll Robertson pupil is less constant, myosis seeming to be more common, and the knee-jerk not so early or continuously lost—no doubt due to the greater resiliency of blood-vessels allowing of better collateral nourishment of sclerosing areas. And yet, if the cause of the disease be an infection, at the same time these more elastic vessels in the young allow ready ingress to all parts of the central nervous system, and the case may be much more rapid, though aberrant, in youth. I have seen, too, the case of a young ataxic, aged twenty-four, with arteries much older for his age, and with marked aresilis, in which the tabes was running the usual routine of slow course, with all the cardinal symptoms. That a man generally lays down line salts in his arteries (arterio-sclerosis) because he is getting old, goes without saying, but that this can occur early also proves treatment can avail much in delaying this stigma of real senility.

Occasionally a joint dystrophy is the most prominent sign of posterior column sclerosis, as in one of the cases seen at the Orthopedic Hospital and Infirmary for Nervous Diseases. These cases are to be studiously watched, so that the unhappy statement of the malady being a chronic rheumatic or tubercular joint may not confront you later. One case at the same clinic also presented the unusual feature of Argyll Robertson pupils in a man past forty years, in whom the Romberg and other symptoms were entirely absent. This is a rare type of tabes, undoubtedly, which will no doubt be slow in developing cardinal symptoms. How to interpret the pupillary inaction to accommodation and yet with normal light reaction persisting, as seen in one of the recent cases in a man aged thirty-five, is difficult. It would seem to show that receptive impulse from light was required to arouse the atonic ocu-motor centres into activity by irritation of them, which were not sufficiently stimulated by any subjective force that the patient could bring to bear—his power of concept expression needed reinforcement from an outside source. These peculiar actions of the pupils, when at all constant, exclude hysterical basis or mere hematrophic malnutrition as the genesis, and bring a neurotrophic failure as causative, whether from sclerosis or inherent weakness of the central neurones. Many of these odd pupillary states may in future serve for the more scientific diagnoses of cases still obscure.

The new phenomenon recently described by Gifford, of contraction of the pupils upon forcible closure of the eyelids, needs more than reflex as an explanation; while the case recently reported to the New York Neurological Society by Sachs, of station becoming much more insecure with the eyes closed in a totally blind man from optic atrophy, may yet be interpreted. Explanation of the lack of the Argyll Robertson pupil in Friedreich's disease is due, no doubt, to persistence of better circulation in glosis rather than in sclerosis existing in the true tabes. Nystagmus in this affection must be caused by nuclear irritation.

Many faulty conditions of equilibrium are suggested by these odd eye phenomena. In a study of the deaf-mute the writer has begun, the fact that in cases of deafness the patients are liable to subjective and objective vertigo, and yet almost never become seasick, is interesting. It throws light upon general medicine, and confirms the view that seasickness is due to central trouble, perhaps the roll of the wave transmitted to the intravestibular lymph or intracanalicular fluid, which is inspissated in the deaf. That the stomach is

*Therapeutic Gazette, October, 1898.
not the cause of seasickness, I can cite cases, especially of one man, aged fifty, with the most pronounced gastro-intestinal indigestion from gastrectasia and auto-intoxication following; and yet his auditory apparatus is so immune that with the worst crises of indigestion he can sail on the roughest seas with no signs of mal de mer proper developing.

The more rapid progress of ataxia when occurring in the African race is to be noted; also the greater liability to phthisis in them is a fact. For study of details of a case of sporous ataxia, with long-delayed knee-jerks, myotic pupils, and family type of deafness, with vertigo, auto-intoxication, and indicanuria, the reader is referred to the University Medical Magazine for April, 1899.

Myelitis is to be distinguished from that generally more extensive malady—so-called syphilis of the spinal cord. The greater complaint of formation (and generally in the lower extremities); the symmetric equality of the whole spastic syndrome, though perhaps less marked increase of knee-jerk in myelitis than in the tertiary specific meningomyelitis; the greater subjective pains in the latter, due to pressure on the sensory nerve roots from the exudate about and in them, therefore the more liability to dysaesthesia or anaesthesias in syphilitic disease; while, finally, early bladder incontinence is most frequent in the specific affection due to the wider lesion. And yet decubitus is less apt to occur in syphilis of the cord where all sensoro-trophic centres and paths are seldom entirely cut off, while the myelitis more frequently destroys the anatomico-physiological structures en masse at special levels of the cord.

Specific cord disease occurs five or six years after the initial lesions, myelitis soon (almost at once) after an exciting cause.

If the case presented for diagnosis between these two affections gives a history that is unreliable or falsely told, questioning as to headache or diplopia will be important points; for at some stage of the early luetic trouble the cerebral meninges will likely have been involved, while the nerves passing out to the eye muscles are pressed upon, or a perineuritis exists.

Why paraesthesia does appear so much sooner and persistently in transverse myelitis seems explained by the general involvement of all sensory paths, and yet it is not infiltrating enough about the roots to cause the severe pain seen in specific disease. Specific cord disease is the more favorable in prognosis.

The deposit of pigment in the skin is not very uncommon in mental and in organic cord diseases, and this may be exaggerated by the overuse of that most valuable drug in neurology—arsenic. In passing, it may be said that arsenic probably acts so favorably in aiding nerve and skin diseases by setting up an irritation in the nerve cells, and in this way stimulating the neurones toward physiological action. In the light of modern cytology this would seem a very probable explanation, rather than making the vague statement that the drug simply acts as an alternative. Trophic influence thus has a physical basis, and by assuming motility of the neurone new fields for the action of drugs and remedial measures are being better learned. Irritation likewise explains the value of the remedy in chronic skin disease.

Barring self-intoxication, extravasations of blood, and direct traumatic ecchymoses, or those of fatty degeneration which are the sequel to pernicious anemia, or of hysterin, it is unusual to find blood leakage other than in hemophilius. That the sudden contraction of muscles may alone cause these purpuric spots is proved in a few recorded instances. Last year the writer reported an odd case of ataxia paraplegia, where these spots had appeared in two separate instances after terrible attacks of pain in the lower extremities. It is probable that the blood is simply forced through the arteriole walls in such exceptional local spasms.

Dr. Mitchell has reported several cases of this unusual condition. The blood is generally reabsorbed without any other trophic disturbance.

Two exceptional cases that were reported at Dr. Mitchell's clinic recently upon the same day illustrate fairly well as to time and symptoms the origin of myelitis and of syphilis of the cord. The most unusual of the cases was that of a man, aged twenty-four, who had had a protracted attack of typhoid fever, with several relapses and profound systemic poisoning. At the end of three months a rather sudden myelitis set up, and he became symmetrically spastic in both lower extremities, without vesical involvement or pain. In the other case, also of a man, aged thirty-five, succeeding the specific infection three years his erratic spinal syphilis gradually developed, with early bladder incontinence, great pain, and spastic arm involvement.

**Cerebro-spinal Palsy.**—Microcephalic and hydrocephalic imbeciles are usually also cases of spastic paraplegia, from the fact of cerebral cortical irritation due to prenatal faults in development or to inflammatory lesions. And in girls so affected, club feet due to contractions are less frequent. Since the writer first reported upon this* a constant search in the study of feeble-minded children has failed to reveal reason for this, except in the fact that in such spastic children boys are more active, so that in going about contractions are often prevented.

A peculiar case of cerebro-spinal paralysis recently came under my care in a very intelligent man, aged thirty-four years, in whom the usual report of a fall at six months of age was given. His trouble was congenital, of course, but it did not manifest itself until the child developed. This man grew to adolescence; he had been unable to walk at ten years, and his parents had been told by his physician that it would be impossible for

*Transactions of the American Academy of Medicine, 1895.
him to live beyond eighteen years. The boy's fat was then enormous. In the active exercise then begun he lost sixty pounds in six weeks. In his fifteenth year, treatment by movements and stretching was begun and persisted in for a year. He got on his legs. The right hand only escaped gross disease contracture, but he has been getting about on crutches ever since in good general health, and is able to earn a livelihood as justice of the peace. This case shows the value of persistence in treatment.

**Chronic Poliomyelitis Anterior.**—This disease is not difficult to diagnosticate in most instances, but occasionally the demeanor of symptoms cross with those of multiple neuritis, and make, therefore, the difficulty of prognosis greater. The case of an otherwise robust man, aged thirty-three, seen April 1, 1899, is in point. He was a non-alcoholic, and was affected, without much pain and little paraesthesia, with a gradual symmetric loss of power of the lower extremities. The knee-jerks were lost, fever had been only transient if at all, and this, with the indication of low location of cord lesion, shown by the patellar reflex being absent, would necessarily imply some bladder involvement, of which there has never been a sign; so, a myelitis proper would at some stage have produced spastic reflexes, and if it had gone beyond this, trophic ulceration would pretty certainly have followed, which also has never been. Then pain or tenderness down the nerve trunks was never prominent. At present, after three years of the affection, there is fibrillary twitching of the muscles of the lower extremities, especially marked over the more wasted adductors and extensors of the thighs, but not the general reaction of degeneration to be found in so widespread a paraplegic neuritis. It is a rare case, no doubt, of spinal chronic progressive muscular atrophy. Peculiar, too, in the case was the gait, the body being held advanced over the thighs at an angle of ninety degrees, so as to prevent backward falling of the trunk, so complete was the muscle paralysis in the recti-extensor group. This was confusing as to possible existing bone disease of the vertebræ.

**Cerebral Disease.**—Abscess of the brain is so fatal a condition that early diagnosis means the only hope, and then by surgical interference. A recent résumé of the literature of this subject, by Joseph Collins,* shows, however, that we are becoming clearer in understanding the generally aberrant, it is true, localizing symptoms. Add to the recognized signs of local brain disease the history of trauma or of middle ear disease; and especially with tenderness over the suspected cerebral or cerebellar region, plus the particularly incomplete, easily-aroused-from delirium, the liability to hemianopsia and less prominent choked disks, as in true tumor formation, and you have a case justifiable for exploratory operation as the only possible hope. Such a case I am at present treating for optic atrophy following septic ear disease, in which the boy, however, was snatched from death by timely trephining by Dr. W. W. Keen.

Dr. C. A. Veasey † has recently reported the odd eye atrophy and central scotoma. I wish here to express a hopefulness in treating such precocious secondary optic atrophy by galvanism, as in this case the boy certainly sees objects better after the treatments.

**Cerebral Edema.**—Can such a pathological entity exist? This has been a much-discussed subject. Certain good authorities contend that it does exist, while other clinicians say no.

Barring toxines, there are other causes leading to such effusion. In the acquired (alcoholic) sanguineous temperaments seen in club men, with urine of low specific gravity, but no casts, albumin, or sugar being found, symptoms such as the following may develop after an engorgement of the stomach: Sudden dizziness, loss of power, say on the right side of the body, with motor aphasia, paraesthesia or obtunding of sensation, semicomatose or entirely comatose condition. By purging with salines, all evidence of palsy disappears in twenty-four hours or so, and, barring general weakness, the patient is well in a few days. Certainly, in such a case as I have seen there was no hemorrhage, and from analogy the patient must have had edema over the left motor area of cortex. Should such a case come to autopsy, it might be even difficult to find edema lost in the section, but this does not prove that serum leakage did not occur at the time. These cases are to be looked for. A guarded prognosis is necessary, as many patients entirely recover if the exciting cause is cut off.

**Traumatic Neurosis or Hystecria.**—Discussion upon this important subject is of interest from the therapeutic standpoint mainly, and is superlative from the medico-legal point of view. The French school of Janet and Sollier, with that of the Germans following Freund, insist that trauma alone produces, by functional disturbance, subconscious states dominating mind and body, and that ergo hysteria is the *casus belli* for the symptomatology of all cases of injury due to any form of grossly non-demonstrable organic lesion in life. That many cases are purely hysterical can but be proved by suggestive cures. That there are others in which such violent commotion of the cord produces nutritional changes of profound degree, even to degeneration and final mixed sclerosis, can in all candor not be denied by seeing the spastic reflexes or nystagmus, true ankle clonus, atrophy of muscles, and all the cardinal signs of insular sclerosis. That there is a background in hysteria painted in the picture of even the known organic cases must be admitted in traumatic spinal neurosis. This does not determine that the consideration of organic disease in the case is not necessary, and if

* American Journal of the Medical Sciences, April, 1899.
proper evidence as to the cause of the trouble is given, damages should be awarded by the courts just as in other accident cases.

The case of M. M., aged fifty-one years, seen with Dr. Hiram Miller, is in point—a medico-legal case in which suit was brought for injury sustained by the man having been thrown from his cart by collision with a street car. He was under surgical care for three months. After the trauma he was unconscious for seven weeks of the time, followed by occasional muttering delirium. He made a very slow improvement, but has been slightly neurotic ever since; has expansive ideas, thinking he is well off, which is at times alternated with melancholy spells. He can not concentrate his mind; is subject to dizzy spells; the knee-jerks are spastic, and abortive ankle clonus exists. There is nystagmus. The pupils and discs are normal; his urine dribbles from him. This patient certainly had insular sclerosis-cerebro-spinal sclerosis due to the accident.

In his book Pearce Bailey upholds the possibility of organic cord disease existing in such cases. In a recent paper, read by Spiller before the Section on Medicine, College of Physicians (April 10, 1899), the writer stated that a cat had been subjected to trauma of the spinal cord without external evidence of injury, and at the post mortem there had been found extensive, though slight degeneration in the anterolateral columns of the white matter.

While I am not aware of histological study having been made in traumatic spinal neurosis in man, from analogy it would seem evident that nutritional sclerosis could occur in man, due to the commotio in vita; and certainly from the clinical symptoms, as before mentioned, organic trouble must exist, albeit at times after months there may be regeneration, just as we know to occur in nerves; and the old idea that such regeneration can not take place within the cord is not to be proved. Some cases of so-called hysterical paraplegia, too, may have been really of this nutritional organic pathology, not disproved by eventual recovery to full health.

Simulation in the vast number of these neuroses, to my mind, can not be entertained, for such patients have never seen the organic disease of which they present often typical signs; and, furthermore, if they had observed such, it would require the skill of a trained clinician to copy.

Patients in cases of this character should be as much entitled to damages, when such a condition exists, if not more so, as in the case of a fractured leg or of partial amputation, for bodily impairment is for years or life.

A profound terminal irritative neurasthenia may indeed result. Six months or a year of treatment will alone give knowledge as to possible recovery. Malingerin must be pretty certainly ruled out of court in most of these cases. It would take more than an expert to do it.

Hebephrenia, or insanity of adolescence, is a peculiar affection occurring in the second half of the first decade of life, and in the first half of the second decade of life more frequently. This was first described among the distinct forms of developmental insanities by von Hecker, in 1871, and has been recently critically studied by Iberg.* I shall not go into detail of these cases, but will mention the finding of severe auto-intoxication in a case of Dr. H. Brooker Mills, and in the case of a girl, aged twenty-two years, now under my care, as shown by persistent constipation for years, and by large quantities of indican found in the urine. The former patient is now convalescing, after four months' rest, feeding, and antiseptic treatment of the gut, while my patient is still in the active stage of the disease, with the prognosis uncertain. [Note, July 11, 1899.—This patient has recovered. Her bowels are now regular, although they had not been so for years.] The fact of lowered nerve resistance in such cases, probably hereditary, is given as causative, but in these two cases an un- doubted self-intoxication was the exciting cause of mental symptoms. When we recall that metabolism is more frequently perverted in the young, we can hope that bodily physic may prove to be the most effectual treatment, with, of course, all known neurological care implied by rest and change of scene.

Sydenham's chorea at times takes on the odd phase of becoming chronic in all its typical symptoms, as in a girl, aged eighteen, who is in no way hysterical.

Two instances of transient glycosuria in neurasthenic men with dilated stomachs (hyperacidity five to five and a half per cent.) recently coming under the care of Dr. Wharton Sinkler, and in my own practice, go toward confirming the close connection between the fermentation catabolism and symptomatology.

Dr. John M. Swan also tells me of a case of acute neurasthenia in which he found ten per cent. glycosuria for days, then it finally disappeared. I can not think this sugar comes from tissue waste in these cases so much as from, perhaps, a hyperacidity (as recorded in the cases I examined the stomach contents of), which causes acidity of blood, and in the liver prevents the proper conversion of the carbohydrates to glycogen by such non-alkalinity. This work in physiological chemistry holds out valuable prospects. The recent work is showing this. Dr. Carstairs C. Douglass reviews some interesting studies in the London Lancet for April 1899,† although the simultaneous urinalyses are not given.

There are many other peculiar nervous diseases, time will not permit of mentioning, save that serious and rare state, uterine peripheral neuritis, simulating renal colic first seen in the practice of Dr. E. Pearce, of Ohio, in a woman who died from a fulminating multiple neu-

* Das Jungendirresein Hebephrenie und Katatone. Sammlung klinischer Vorträge, No. 224, October, 1898.
† The Contents of the Stomach in the Gastric Ulcees of Locomotor Ataxia.
ritia primarily beginning in the uterus, following cold. Such a case came under my own care recently, and was most difficult to distinguish from renal colic. The pain is perhaps more constant and lower than in nephralgia, and on questioning you will find a history of uterine disturbance, amenorrhoea, preceding the attack. My patient recovered slowly with atrophied muscles of the legs.

Finally, I wish to remind you that any outside cause of mental depression should be looked for. Worry is the cause of "wear and tear," undoubtedly, so that we should look all the way round the circle for the missing segment before these morbid symptoms can be eradicated.

Superfluous hair is the cause of secretiveness, depression, and final neurasthenia in not a few women, and should be corrected just as fully as you would have an active gynecological lesion repaired. This work of depliation can now be done scientifically and permanently by electrolysis.

It is well for the broad physician to look up a diplomatic trained nurse, teach her the use of this accurate agent, and then put his cases in which the treatment is needed under her care. Much of the quackery practised in these lines with the aid of various arsenical pastes, I think is due to the fact of the neurologist not paying attention to this important measure. In a case under my care the patient has been cured by this operation, which was carried out by a trained woman under instruction; a good mind has been reclaimed.

A REPORT OF TWO CASES OF TYPHOID INFECTION WITHOUT ANY INTESTINAL LESIONS.

By August Jerome Lartigau, M.D., Assistant in Pathology and Bacteriology, Seden Hygienic Laboratory, Albany, N. Y.

The belief that typhoid infection may exist without any lesions of the intestine is by no means one of recent origin. So long ago as the early half century Louis referred to this possibility in Observation LII of his Recherches anatomiques, pathologiques et therapeutiques sur la fièvre typhoïde, a case having all the clinical symptoms of typhoid fever, in which, however, the accropsy had failed to reveal any implication whatever of the intestinal tract. Litten (1), Moore (2), Church (3), and other observers have also recorded similar examples in which no intestinal disease existed. Although these observations possess little value as scientific contributions to this subject for lack of a bacteriological basis, nevertheless they are interesting as appreciations of the existence of an atypical type of this disease.

The bacteriological era in the investigation of these forms begins with the study of a case by Banti (4) in 1887. The patient was a woman, fifty-one years old, who during life presented the usual symptoms of enteric fever. Death took place on the twenty-eighth day of the disease. At the autopsy no intestinal lesions were found, but the spleen and mesenteric glands were swollen. In the sections from these tissues bacilli morphologically similar to the Bacillus typhosus were found. Thue (5) in 1889 described the case of another patient, in the spleen and kidney of whom he professes to have found the bacillus of typhoid fever.

With the publications of Vaillard (6), Chante-messe (7), Karlinski (8), Vincent (9), Guarnieri (10), Du Casal (11), Kühnau (12), Pick (13), Meunier (14), Beatly (15), Flexner and Harris (16), Cheadle (17), Chiari and Kraus (18), Nickolls and Keenan (19), Lartigau (20), and Bryant (21), accuracy in methods of study become progressively better and the results more convincing.

To the foregoing cases I wish to add two others, for the histories of which I am indebted respectively to Dr. Samuel B. Ward and Dr. Willis G. MacDonald, of Albany, New York:

Case I.—Charles P., single, fifty-one years of age, colored, was admitted to the Albany Hospital on February 28, 1899, suffering with pain in the head, back, chest, and limbs; there was also some fever.

Family History.—Father died of "dropsy"; mother succumbed to heart disease, aged fifty-six. A brother and two sisters are living and well.

Personal History.—When ten years old he had an attack of "the gravel," accompanied by paroxysms of pain in the back. For many years the patient has suffered from repeated attacks of acute articular rheumatism, affecting the knees, elbows, ankles, and smaller joints. No other illness.

Present Sickness.—About two weeks ago he was taken ill with acute pain in the head, back, chest, and limbs. Within two days he had a cough and marked shortness of breath; had been in bed for nine days previous to admittance, during which time there had been no amelioration of the symptoms.

On admission, the temperature taken in the axilla was 99.4° F.; pulse, 92 and regular; respirations, 32. The patient is of medium build, moderately well nourished; answers questions intelligently. Pupils equal and react to light; conjunctive suffused. Tongue is coated with a brown fur on its dorsum. No odema; no eruption on skin; no nasebleed; bowels constipated. The heart sounds are somewhat feeble, but otherwise apparently normal. Over both lungs anteriorly and posteriorly a few coarse moist râles may be heard. Spleen is not enlarged. The hepatic dullness is apparently normal. The abdomen is slightly tympanitic; no iliac gurgling or tenderness.

March 2d.—The examination of the urine is negative for albumin and sugar. Microscopically the sediment shows nothing pathological. Temperature in the mouth, 99.4° F. last evening; pulse, 88.

4th.—Anorexia is almost complete; temperature and pulse about the same. The heart is normal; over both lungs fine moist râles. Spleen is not palpable. Some occipital headache.

5th.—Eleven a. m., temperature, 102.4° F.; pulse, 130, irregular and diastolic. During the afternoon
yesterday had a succession of convulsions, rapidly recurring at intervals, at first, of ten or fifteen minutes; toward evening, however, became more infrequent. At this time both pupils were dilated and equal, head drawn back. Chill during the night: heart sounds feeble and muffled; lungs same as yesterday. Patient died at 3 p.m.

Autopsy (two hours post mortem).—Anatomical diagnosis: Typhoid fever without intestinal lesions; chronic interstitial nephritis; broncho-pneumonia, with edema of both lungs; chronic adhesive pleuritis; hypertrophy of left ventricle; red and white infiltration of liver and right kidney; cloudy swelling of the liver and kidneys; concentric hypertrophy of the bladder; fatty atrophy of the aorta; chronic gastritis; pyogenic infection of the lungs.

Body 160.5 centimetres long, moderately well built, fairly well-nourished negro. Rigor mortis well marked in upper and lower extremities. Post-mortem lividity of the dependent parts. Both pupils widely dilated, the left less so than the one of the opposite side. No evidence of cicatrices on glans penis. Muscous membranes pale. Muscles of thorax and abdomen reddish brown color.

Brain and cord not examined. Abdomen: Peritoneal cavity free from any excess of fluid; both layers of the peritoneum are normal in appearance. Omentum contains a small amount of fat; omental glands not enlarged. Foramen of Winslow patent. Diaphragm, on the right side, fourth rib; fifth space on the left side in the mammary line. Thorax: Both pleural cavities free from fluid. Precordia measures twelve by nine centimetres; both layers of the pericardium are smooth, glossy, and free from injection. The heart is very large; distended with fluid blood and red and chicken-fat post-mortem clots; endocardium smooth; valves normal; left ventricle measures two centimetres in thickness, consistence firm, and on section the color is brownish-red with streaks of yellow. Both lungs are bound down laterally and posteriorly by old firm adhesions; upper lobes congested and emphysematous; lower lobes on both sides present broncho-pneumonic areas surrounded by oedematous lung. Bronchi: Muscous membrane intensely congested and covered with a small amount of yellow mucus. Pulmonary vessels normal. The spleen is bound down to abdominal wall and omentum by old, firm fibrous adhesions; organ measures 8 x 6 x 2.75 centimetres; capsule smooth, not wrinkled; consistence: about normal; on section, of a deep reddish-brown color; trabeculae not increased in amount; Malpighian bodies prominent. Liver: Not enlarged, capsule smooth; on section, organ is an opaque grayish color, lobules indistinct. The kidneys are normal in size; consistence: not increased; losses of kidney substance apparent here and there on the surface. On section, the organ is pale; cortex irregularly diminished; cortex markings distinct; glomeruli visible; medulla and pelvis normal. Both adrenals, ureters, and oesophagus normal in appearance. Pancreas is firm, and on section presents no abnormality. The retroperitoneal and mesenteric glands are not swollen. Prostate and testicle show no changes. The bladder is diminished in size; walls markedly increased in thickness, the average being one centimetre; mucous membrane congested, and shows small pinhead and larger discrete and confluent submucous hemorrhages. Stomach: Not enlarged; walls about normal in thickness; mucous membrane covered with sticky mucus and irregularly atrophied. The large and small intestine show absolutely no change whatever. Aorta: Slight fatty atheroma.

Microscopical Examination.—The tissues studied were all hardened in ninety-five-per-cent. alcohol. The sections of hardened tissues were stained with hematoxylin and cosin, Van Gieson's picro-acid-fuchsin, with Weigert's fibrin stain, and by Flexner's methylene-blue method.

The histological examination of the heart showed, in addition to an increase in the thickness of the epicardium, a well-marked chronic interstitial myocarditis. The sections of lung in some places showed the lesions of emphysema; elsewhere those of emphysema and edema; and finally those from the lower lobe presented the ordinary appearances of broncho-pneumonia and edematous lung. Liver: The portal spaces showed a moderate cellular increase, made up largely of small round cells. Besides cloudy swelling of the liver cells a few of the “lymphomata” commonly present in ordinary cases of typhoid fever, were made out. Some congestion of the spleen was made out, but no focal necroses were detected. The kidney sections showed a moderate degree of chronic interstitial nephritis, with a well-marked endothoracic of the finer blood-vessels. The examination of the pancreas, adrenals, and testicles added nothing to the macroscopic findings.

Prolonged and minute examination of sections of the broncho-pneumonic lung, liver, spleen, and kidney stained with Weigert's fibrin's stain failed to demonstrate any micro-organisms; but sections from the liver and spleen stained by Flexner's methylene-blue method showed clumps of short, thick bacilli in the tissues. Treated by Flexner's method, the broncho-pneumonic lung also contained bacilli, but morphologically differing in being longer and more slender.

Bacteriological Examination.—Cover slips from the areas of broncho-pneumonia contained a large number of polymorphonuclear leucocytes, a few epithelial cells, *debris*, and a moderate number of slender bacilli of medium length, which readily decolorized by Gram's method. Plate cultures in agar were made from the blood of the heart, broncho-pneumonic lung, liver, spleen, gall bladder, kidney, and urine. Those from the heart's blood and spleen remained sterile at the end of three days' incubation at 37.5° C. The culture from the broncho-pneumonia contained a profuse pure growth of the *Bacillus pyocyaneus*. The plates from the liver, gall bladder, kidney, and urine all contained a single organism morphologically similar in all the cultures. The morphological and cultural characteristics of this organism are as follows:

*Agar-agar slant:* At the end of twenty-four hours a thin, moist, translucent gray or white growth along the surface.

*Blood serum:* The appearance of the growth upon this medium is practically the same as upon agar slants.

*Potato:* Scanty, moist, almost invisible growth along the line of inoculation.

*Gelatin stab:* A white growth along the inoculation line. No liquefaction of the gelatin at the end of twenty days.

*Litmus milk:* The medium at the end of forty-eight hours becomes faintly pink, but at no time becomes coagulated.

*Bouillon:* Diffusely cloudy in twenty-four hours.

*Dunham's peptone medium:* Diffusely cloudy, like the bouillon. No indol reaction.
Glucose and lactose agar: Growth along the inoculation tract, but no evidence of gas formation.

Preparations from different media showed slight morphologic variations, notably the growths on potato; but generally the organism appeared as a rather short, thick bacillus with rounded ends, which quickly decolorized by Gram's staining method. In hanging drop preparations from young bouillon cultures (twenty-two to twenty-six hours) the bacilli were actively motile. By Pitfield's method the flagella (ten to twelve) were well brought out with the characteristic peritrichous arrangement. The organism was tested with sera from three known cases of typhoid fever, and a positive Widal reaction was obtained in each instance.

**Bacteriological Diagnosis: Bacillus typhosus.**—Blood obtained post mortem from the right auricle was tested with a twenty-four-hour-old bouillon growth of the laboratory stock culture. In a dilution of one to thirty a positive reaction was obtained in twenty minutes; with a dilution of one to fifty the agglutination and immobility were complete in forty-five minutes. With the typhoid bacillus from this case, in a dilution of one to fifty, the reaction was complete in forty minutes.

**Case II.**—Mary L. J., married, aged thirty-one years, American; entered the Albany Hospital March 11, 1899, complaining of general abdominal pain and tenderness, most marked in the region of the left iliac fossa.

**Family History.**—Father died of tuberculosis. Mother alive and well. Two brothers died of meningitis in infancy. One brother and four sisters alive and well.

**Personal History.**—As a child she suffered from measles, chicken-pox, and mumps. During the month of November, 1898, the patient was sick for three weeks with an acute febrile malady which was diagnosed as typhoid fever.

**Present Illness.**—This began about five weeks ago, when she was taken ill with sharp paroxysmal pains starting behind in the lumbar region and extending forward on either side toward the umbilicus. For the first two weeks the attacks were infrequent, but since have progressively increased both in frequency and severity, so much so that at time of admission the pain was constant, and referred in large part to the iliac region on the left side. The last menstruation occurred in the first week of January, 1899.

On entrance into the hospital the temperature taken in the mouth was 102.4° F.; pulse, 118, regular, of fair volume, and not diuricotic; respirations, 27. The build was slim, body moderately well nourished; intelligence good. Pupils were normal and reacted to light; conjunctiva normal. Tongue was covered on the dorsum with a thin white fur. No oedema. No eruption on skin. Examination of the heart was negative. The lungs gave no evidence of any abnormality. Spleen was not palpable; the liver was apparently normal. The abdomen was tender, more particularly on the left side in the iliac fossa. Palpation was negative. Vaginal examination showed a normal cervix. Bimanual palpation: Uterus about normal in size, the body directed forward and freely movable. On the left side an indefinite mass of the size of a hen's egg, not freely movable and firm to the touch. The examination of the opposite side was negative.

**March 12th.**—An abdominal section was done at 12.25 P.M. Diagnosis of ectopic pregnancy confirmed, and removal of left tube and ovary with gestation sac. Patient returned in good condition; pulse, 125; respiration, 30. At 6 P.M. complained of pain in abdomen; pulse, 115, and intermittent; temperature, 101.2° F. Urine normal.

**13th.**—Considerable nausea and vomiting; evening temperature, 100.6° F.; less pain in abdomen.

**14th.**—Nausea and vomiting persisted. Complained of headache; restless, temperature, 101.0° F.; pulse regular, good volume; heart sounds normal. Lungs showed nothing abnormal. Slight blood-stained discharge from uterus.

**15th.**—Dyspepsia during the night; mind clear; respiration, 36; pulse, small volume, intermittent, 150 per minute; temperature at 8 A.M., 100.2° F.; at 1 P.M., 102.6° F. Died at 2 P.M.

**Autopsy** (an hour and a half after death).—Anatomical diagnosis: Typhoid fever without intestinal lesions; laparotomy wound (removal of left tube and ovary for extra-uterine pregnancy); acute splenic tumor; cloudy swelling of the liver and kidneys; endometritis; triple phosphate calculus in pelvis of right kidney; typhoid and streptococcus infection of uterus; diplococcus lanceolatus septicaemia.

Body 161 centimetres long, slim build, and sparsely nourished. Surface of the body generally pale. Rigor mortis absent in upper and lower extremities. Slight liver mortis of the dependent parts. Pupils midwide and equal. Mucous membranes pale. In the midline of abdomen was a linear incision eleven centimetres long, extending from the pubis upward, which appeared perfectly healthy.

**Brain and cord not examined. Abdomen:** Parietal peritoneum presented a normal appearance; the visceral layer was smooth, glossy, and moderately injected, especially that portion over the lower third of the ileum. Omentum contained a few discrete pinhead to pea-sized hemorrhages. Foramen of Winslow not patent; diaphragm on the right side, fourth space, on the left side, fifth space, in the mammary line. Thorax: Both pleural cavities were free from fluid. The pericardium was normal; the heart was distended with fluid blood and some red clots, and showed no abnormality. Both lungs were free from adhesions, crepitant, and on section light pink in color. Bronchi and pulmonary blood-vessels normal. The spleen was adherent to the omentum by a few old, firm bands; organ measures 15×9×5.5 centimetres; capsule smooth and not wrinkled; consistency diminished; cut surface reddish-brown; trabecula normal and pulp apparently augmented; Malphighian bodies prominent. Liver increased in size; capsule smooth; consistency softer than normal; on section, an opaque grayish color and lobules indistinct. Gall bladder moderately distended with thick, dark-colored bile. Kidneys slightly swollen, especially the cortical portion of the organ; consistency about normal. The pancreas, suprarenal capsules, and retro-peritoneal glands showed nothing abnormal. The same may be said of the aorta, stomach, bladder, and vagina. The mesenteric lymph glands were not swollen. The intestine showed absolutely no evidence of past or recent changes; the mucous membrane was normal in appearance. The uterus measured 5.5×4×3 centimetres; the consistency was normal; peritoneal surface was smooth, glossy, free from adhesions, and moderately injected. The walls were not increased in thickness; cavity patent; endometrium soft, red, congested, markedly so in fundus of the organ. Covering the mucosa
was a considerable quantity of thick, sticky, haemorrhagic mucoid material.

**Microscopical Examination.**—The tissues studied were all hardened in ninety-five-per-cent. alcohol. The sections of hardened tissues were stained with haematoxylin and eosin, Van Gieson’s picric-acid-fuchsine, and by Flexner’s methylene-blue and Gram-Weigert staining methods.

Histological examination of the heart showed nothing beyond a slight degree of fragmentatio myocardii with dilatation of the capillaries and small veins, in both of which blood was seen, showing a leucocytosis of the multinuclear form. The sections from the lung, intestines, pancreas, and adrenals added nothing to the macroscopic findings. In addition to well-marked cloudy swelling and some more or less localized areas of fatty degeneration, the liver showed no other changes. The “lymphomatia” commonly found in the liver of ordinary cases of typhoid fever were entirely absent, as were also any areas of focal necrosis. In the sections of the spleen some hyperplasia of the lymph cells was noted with considerable congestion. In the kidney, the epithelium of the convoluted tubules was markedly swollen, granular, and often devoid of nuclei; some of the epithelial cells were desquamated. Uterus: The superficial strata of epithelial cells were desquamated, the remaining cells being swollen and occasionally having lost their nuclei; the submucous and mucous tissues were considerably infiltrated with polymorphonuclear leucocytes and small round cells. The musculature presented a perfectly normal appearance.

Sections of the kidney and lung stained with Weigert’s fibrin stain showed very few diplococci, limited to the small blood-vessels. In sections of the liver, ileum, and uterus stained by Flexner’s method occasional bacilli (a few clumps in the liver) morphologically similar to the Bacillus typhosus could be distinguished; in the sections of the uterus the bacilli were only made out in the mucosa. Cocci were likewise detected in the mucosa of this organ.

**Bacteriological Examination.**—Agar and gelatin plate cultures were made from the blood of the heart, left lung, spleen, liver, gall bladder, kidney, operation wound, peritoneal cavity, and uterine cavity.

The cultures from the lung, operation wound, and peritoneal cavity remained sterile. From the heart’s blood and spleen a pure growth of an oval or elongated coccus, sometimes in pairs, more often single, was isolated, corresponding in its tintorial and cultural reactions to the diplococcus lanceolatus. It was pathogenic for rabbits both in subcutaneous and intravenous inoculations.

The plate cultures from the uterus contained two sets of colonies—about twenty-five to thirty small pinpoint, gray, translucent, discrete colonies in the depths of the medium. Under the low power they appeared finely granular, oval in form, with a regular outline; the second set consisted of seventy or eighty discrete pinhead-sized or slightly larger white colonies, which by transmitted light had a yellow tinge. The latter were made up of not very long, rather thick bacilli, while the former consisted of round cocci, sometimes single, grouped, or in short chains. Culturally the colonies made up of bacilli behaved as follows:

**Slants of agar-agar:** A profuse, slightly elevated, moist white growth with regular margins.

**Blood serum:** Growth was equally rapid to that on agar-agar, and presented a similar appearance.

Gelatin stab: Fine, somewhat scanty white growth along the line of inoculation. No liquefaction of the gelatin at the end of sixteen days.

**Potato:** A moist, glistening, scanty growth which was just perceptible to the eye.

**Litmus milk:** Very slight acidification of the medium, but no coagulation of the milk.

**Alkaline bouillon:** The medium became uniformly cloudy at the end of twenty-four hours.

**Dunham’s peptone solution:** The appearances were identical with those of the bouillon. No indol reaction could be obtained.

Stab inoculations into glucose, lactose, and saccharose agar showed a white growth along the line of inoculation, but gave no evidence of gas formation.

Hanging-drop preparations from twenty-four-hour-old bouillon cultures contained bacilli which were actively motile. In cover slips from similar young cultures, stained by Pitfield’s method, could be seen bacilli having ten to fifteen flagella (peritrichial arrangement). Tested with sera from known cases of typhoid fever, positive Widal reactions were obtained. Blood taken from the subject post mortem gave a positive Widal reaction with this bacillus as well as with other known cultures of the bacillus of typhoid fever.

**Bacteriological Diagnosis:**—**Bacillus typhosus (Eberth-Gaffky).**—Pure growths of the bacillus typhosus culturally and morphologically similar to the above were isolated from the liver, gall bladder, and kidney. The cocci associated in the uterus with the typhoid organism was identified as the *Streptococcus pyogenes*.

Some hesitancy in the acceptance of the second case herein reported as an example of typhoid infection without any intestinal lesions very naturally finds expression with the cognizance of obvious difficulties, a complicating factor in the form of a history of probable typhoid fever about four months before. The remarkable viability of Eberth’s bacillus in the human economy has been demonstrated by the observations of von Durgen (32), who, fourteen years and a half after the fever, found the bacilli in an abscess of the gall bladder; Busehke (23), who, eight years after the attack, cultivated typhoid bacilli from an abscess elsewhere; and Bruni (24), Sultan (25), Chantemesse (26), Parsons (27), Péan and Cornil (28), Chantemesse and Widal (29), Orloff (30), Kleinn (31), Berg (32), Lockwood (33), and others, all of whom published cases of a more or less similar character. With a keen appreciation of the importance of this knowledge to such a possibility in this case, the probability nevertheless seems to us unlikely and remote in view of the wide dissemination of the bacilli in the liver, gall bladder, kidney, and, moreover, the most uncommon localization, in the uterus.

**Apropos of polybacterial infections,** this case is not without some interest: the presence of a diplococcus lanceolatus septicaemia, multiple foci of infection with the typhoid organism, and the association of the *Streptococcus pyogenes* and the Bacillus *typhosus* in the uterus.
THE EARLY RECOGNITION AND MANAGEMENT OF MALIGNANT DISEASE OF THE DIGESTIVE SYSTEM.*

Br. MAX EINHORN, M. D.

MALIGNANT diseases or growths of the digestive tract comprise the different types of cancer and sarcoma. As the latter are much less frequent, and usually present similar symptoms and consequences as the former, we will limit our remarks to cancer.

Cancer has always been recognized as the gravest of diseases, bringing with it the surest prospect of death. This axiom remains true even to-day, with the only difference that we must add, "if not interfered with surgically."

Surgery has indeed achieved its greatest triumphs in the removal of malignant diseases (tumors) in their early period of development, thus checking their further spread. Cancer of the breast and of the uterus are nowadays operated upon usually with a fair chance of non-recurrence of the growth.

These successful operations show that cancer is primarily a localized and not a systemic disease, as was formerly believed.

The more deeply the malignant growth is situated, the more difficult becomes its recognition and the less fruitful, even its surgical treatment. For cases of non-recurrence of malignant diseases of the digestive tract (with the exception of the anus and rectum) are as yet extremely few. This, however, is not the surgeon's fault, but rather that of the clinician. For, judging from analogy, malignant tumors, if discovered early enough, should be just as successfully removed from the digestive tract as elsewhere. It is, therefore, the just aim of the clinician to perfect his diagnostic ability with regard to malignant disease.

The stomach tube, and in conjunction with it the chemical analysis of the gastric contents have marked a decided advance in this direction; transillumination of the stomach may also, in favorable instances, be of some service. But we must concede that our methods are still comparatively crude, and as a rule permit us to recognize the malignant affection at a stage when it has already progressed to a considerable extent.

Before discussing the diagnosis it may not be amiss to make a few remarks with regard to etiology.

The etiology of cancer has been investigated by numerous scientists all over the world. But, unfortunately, the goal has not as yet been reached. Cohnheim's theory of the origin of tumors by embryonic cells which have remained dormant and at a certain period

---

* Read before the Fifth District Branch of the New York State Medical Association, at its fifteenth annual meeting, held in Brooklyn, May 23, 1899.
awake with renewed energy to attain gigantic development, is known to us all. A similar theory has been recently propounded by Ribbert, who assumes that a tumor develops from cells which accidentally have strayed from their place of origin and have been carried into some other tissue. Being foreign elements they extend their growth, not heeding the neighboring organs. Neither of the two theories has found general acceptance. Sporozoa have been believed by some writers (Pfeiffer, Hutchinson, Park, Metschnikoff) to be the cause of cancer. But these so-called parasites which have been discovered in cancerous tissue are most probably nothing else than degenerated and dried-up portions of cells, and nothing has as yet proved their real parasitic nature.

One factor which, though not directly concerned in the origin of cancerous tumors, creates a decided predisposition for their development, is repeated irritation. This etiological factor has been established through numerous statistics, and it seems to me to be most pronounced in the digestive tract. Those places along the digestive canal which are subjected to the most marked mechanical irritations are also most often the seats of malignant disease. Thus the stomach, which receives the food in a comparatively coarse state and is exposed to great mechanical as well as chemical irritations, is, according to Virchow, the organ most often attacked with cancer. And here, again, the cardia, and especially the pylorus, are chiefly involved. The cardia is subjected to the friction of the food passing through it, while the pylorus is constantly irritated by the acid chyme as well as by some coarse particles of food which, by the churning motions of the stomach, are constantly carried toward that outlet without passing it. The small intestine, through which the chyme passes in its greater part in liquid form, is very seldom attacked with cancerous disease; while the large bowel, in which the fecal matter assumes a more solid consistence, shows already a greater percentage of cancerous disease. These relations are best demonstrated by the statistical data given by our worthy president, Dr. J. D. Bryant. In a hundred and ten autopsies of patients suffering from intestinal cancer this writer found the neoplasm located six times in the small intestine, seven times in the cecal and ileo-cecal regions, nineteen times in the transverse colon, and seventy-eight times in the sigmoid flexure and rectum.

I shall now describe in a cursory manner under what conditions the diagnosis of cancer of the different parts of the digestive apparatus is justifiable:

I. Oesophagus and Cardia.—Gradually developing dysphagia and the presence of a stricture in the oesophagus, especially if a particle of tumor showing the characteristics of cancer has been brought up with the tube, or the above symptoms, with frequent small hemorrhages, make the diagnosis of malignant disease positive.

II. Stomach and Pylorus.—With reference to the stomach and pylorus I* have suggested the following rules upon which to base a positive diagnosis of cancer:

1. If particles of tumor are found (in the wash water or in the tube) which under the microscope reveal the characteristic picture of a malignant growth.

2. The presence of a more or less large tumor with an uneven surface, belonging to the stomach and associated with dyspeptic symptoms.

3. The presence of a tumor associated with frequent hematemesis.

4. Constant pains, frequent vomiting, ischochyinia, emaciation—all these symptoms being quite permanent and not extending over too long a period of time (six months to a year).

5. Tumor and ischochyinia.

6. Emaciation, ischochyinia, presence of lactic acid.

7. Constant anorexia and pains, not yielding to treatment, accompanied by frequent small hemorrhages of coffee-ground color.

III. Small and Large Intestines.—For the small and large intestines the following points will prove of service in making the diagnosis of cancer:

1. If by ademinal or rectal palpation a tumor can be detected which is situated in the small or large bowel, and accompanied by symptoms of cachexia and disturbances of defecation.

2. The presence of a tumor as just described, and the discovery of small particles of the neoplasm in the evacuation giving microscopically the appearance of a cancerous growth.

3. Gradually increasing disturbances of the bowel for a few months in a heretofore healthy person, accompanied by cachexia and symptoms of a beginning or already developed structure of the bowels, and the presence of a small particle of growth in the stools giving, as above, microscopically, the picture of cancer.

After having thus summarized the conditions under which a positive diagnosis of malignant disease of the digestive system can be made, let us see how the diagnosis can be established early. There are no new points which I can suggest for this purpose. A thorough examination of the physical state of the patient—paying strict attention to all our usual methods in this direction—and a full knowledge of the history of the case, will permit us to discover malignant disease comparatively early. In quite a number of instances we shall not be able to make a positive diagnosis of cancer, but our suspicions of a malignant trouble will be aroused. Here frequent examinations and further observation of the case are of intrinsic value. Sometimes examination under narcosis may afford better results. In rare cases, in which a probable diagnosis of malignant disease can be made, an exploratory laparot-

omy with the view of establishing the diagnosis and performing a radical or palliative operation will be required.

Having made the diagnosis of malignant disease, the question arises, What shall be done for the patient? The following may be given in brief as an answer applicable to the digestive system in general:

1. Whenever the tumor is accessible for operation, and there is the slightest hope of curing the patient, the complete extirpation of the growth should be performed.

2. If the tumor is not accessible for operation, or the entire removal of the malignant disease is practically impossible, palliative operations which serve to alleviate suffering and prolong life should be undertaken in cases requiring them.

3. Cases of malignant disease operated upon, as well as those without operation, require for their treatment and management a skillful physician, who is able to lessen suffering and nearly always also to lengthen life, even under the most trying conditions.

After these general statements, permit me to say a few words with regard to the special management of malignant disease in the different portions of the digestive tract.

Cancer of the esophagus and cardia does not for the present permit of any radical operation. As soon as the diagnosis is positive and the dysphagia is such that the patient is not able to partake of sufficient liquid and semiliquid food, in order to maintain his weight, gastrostomy should be performed wherever feasible.

Cancer of the stomach and the entire intestinal tract should be operated (i.e., removed), if discovered early enough. Practically the outlook for a cure after a radical operation of some portion of the intestinal canal becomes less encouraging the farther away from the anus the tumor is situated. Malignant disease of the pylorus can often be recognized quite early through the ischochymia which it usually produces. In these instances a laparotomy should be performed as soon as possible and the pylorus resected, with establishment of a new communication between stomach and duodenum if possible; if not, a gastroenterostomy alone should be made. The latter operation is in many cases of decided benefit, facilitating nutrition and rendering the pains less.

Cancer of the lesser curvature of the stomach or of the posterior wall is usually recognized quite late, rendering radical operations practically impossible. If cardia and pylorus are not involved, there will be no need of any operation, and the usual palliative remedies should be administered. The same may be said also of cancer of other portions of the stomach not involving either cardia or pylorus, in which a radical operation does not appear possible.

Cancer of the rectum can be recognized at an early stage, and resection of the neoplasm is here accompanied by brilliant results. If the tumor is located farther up in the large bowel or the small intestine the results of an operation are not so promising, for here the recognition of the growth is possible only at an advanced period, and by that time often adhesions with other organs and cancerous infection of the glands have already taken place.

Excision of the tumor and resection of the intestine in the neighborhood of the neoplasm, with an end-to-end anastomosis, should be practised whenever feasible. In case, however, total resection is impossible, an enterocolostomy or enterocolostomy, or, if the cancer is situated in the rectum, a colostomy (artificial anus) will be of benefit. These operations are palliative in nature and prolong life, at the same time making it more comfortable. They are intended to allay the symptoms of obstruction and to carry the faecal matter over a new route, not passing through, and thus not irritating the cancerous area. In some instances of inoperable cancer of the rectum curettage, followed by the application of the thermo-cautery, may be of benefit for a short period.

20 EAST SIXTY-THIRD STREET.

Therapeutical Notes.

Maragliano's Powders for Bronchorrhea.—The Riforma medica for May 15th gives the formula as follows:

B. Benzoic acid .......................... 30 grains;
Tannin .................................. 15 "
M. Divide into five powders. One to be taken every two hours.

The Treatment of Nasal Hydrorrhea.—M. Larvoyez (Progrès médical, June 10th) recommends that during the first week the patient should take daily about one two hundred and sixtieth of a grain of sulphate of atropine and a thirty-fifth of a grain of sulphate of strychnine. During the following week this dose may be doubled, and, says the author, even tripled in the third week. A cessation for ten days is then counselled, after which the course may be renewed.

A Lotion for Pityriasis Capitis.—The Riforma medica for March 29th gives the following formula:

R. Resorcin ............................... 8 parts;
Alcohol, of each ........................ 15 "
Glycerin, ............................... 10 "
Rose water .............................. 120 "
M. S.: To be applied with friction.

Picot's Vesical Injection for Gonorrhoeal Cystitis.—The Riforma medica for April 8th gives the formula as follows:

R. Guaiacol ............................... 5 parts;
Iodoform ............................... 1 part;
Sterilized olive oil ........................ 100 parts.
M. From ten to twenty drops to be injected into the bladder once or twice a day.
THE BURSAE MUCOSAE OF THE HIP, AND THEIR DISEASES.

This subject, which seems to have escaped general attention, has recently been studied by Dr. R. Zülker (Deutsche Zeitschrift für Chirurgie, 1; Centralblatt für Chirurgie, May 27th), who was led to make the investigation by observing a case of chronic subiac bursitis which had been mistaken for one of fracture of the neck of the femur with excessive formation of callus. He has particularly studied the inflammatory affections of the bursae in the region of the hip, which, being rather rare, have been too little regarded in diagnosis. He finds that the most important of these bursae, from the practical point of view, are the one situated beneath the ilio-psoas muscle and the one found under the aponeurosis of the gluteus maximus, above the great trochanter. As these two are the most constantly present, they are the commonest seats of inflammatory hygroma, cysts, and abscesses.

The author has found published accounts of sixty cases of disease of the bursae of the hip. In fourteen of them the subiac bursa was inflamed, and in the rest the trochanteric bursa. In the opinion of the Centralblatt's writer, Dr. Meinhard Schmidt, of Cuxhaven, these histories are not all of equal value, for in many of the cases the correctness of the diagnosis does not seem to have been established beyond doubt; nevertheless, they are of service in clearing up these diseases from the clinical standpoint. It appears that subiac bursitis is its seat under Poupart's ligament, near the ilio-psoas, whence a large swelling, reaching even to the middle of the thigh, may proceed. This swelling is smooth, generally more or less tender on pressure, and fluctuating as a rule, but if it is very tense it may appear to be solid. By its pressure on the crural nerves it may give rise to crural neuralgia, and by pressing on the great vessels it may occasion venous thrombosis. By interfering with the movements of the hip joint it may lead to the suspicion of dislocation. For the most part, the limb is in an attitude of abduction, outward rotation, and slight flexion, simulating that of morbus coxarii; but the absence of shortening, the presence of the great trochanter in the Roser-Nélaton line, and the freedom of the joint itself from tenderness serve to exclude hip-joint disease. In the majority of cases injury plays a part in the etiology; more rarely the trouble is due to rheumatism, syphilis, gonorrhoea, or the like. The formation of these hygromata is extraordinarily slow, sometimes extending over several years.

Apart from their situation, the inflammatory affections of the trochanteric bursa are strikingly like those of the subiac. They must be distinguished, not only from coxitis with its circumarticulate abscesses, but also from extra-articular osteitis of the trochanter. It is to be remembered that the trochanteric bursa is often the subject of tuberculous disease, more frequently on the left side than on the right.

In these days of antiseptic treatment of wounds the diseases of the bursae mucosae may be dealt with more radically than was formerly the case. Puncture, compression, injections of tincture of iodine, etc., should not be entirely discarded, but the removal of the hygroma, together with its bursa, is a surer procedure.

THE NEW CORPS OF WOMEN NURSES FOR THE ARMY.

A CIRCULAR recently issued from the surgeon-general's office gives the regulations governing the "female nurse corps" of the army. The corps is to consist of chief nurses, nurses, and reserve nurses. In every hospital to which women nurses are assigned one of them shall be a chief nurse. The women of the corps are all to be under contract. To obtain a contract, a woman must present a physician's certificate of her health, on an official blank form; she must be a graduate of a hospital training school for nurses which gives a thorough professional education, including at least two years' residence in the hospital; and she must be indorsed by the person who is at the time of her application the superintendent of her training school and also by the superintendent under whom she was trained. It is specified that these requirements may be waived wholly or in part in the cases of "dietists," women who are proof against yellow fever, and women who have rendered satisfactory nursing service in the army during the Spanish-American war. A "dietist" is a nurse assigned to supervise the preparation of food for patients who are unable to eat the usual ration, or to prepare it herself, besides performing such other duties as may be assigned to her by the chief nurse of her hospital.

A nurse is first taken on probation, and she signs a contract to serve for at least a year, unless sooner discharged, but "immunes" needed for special duty
are not required to sign for any definite length of time. If a nurse is found unsatisfactory, her contract may be annulled; it will not be annulled at her own request save for reasons satisfactory to the surgeon-general; and the contract of a nurse on duty in the United States whose service has been entirely satisfactory will not be annulled except by authority of the surgeon-general.

For service in the United States a nurse will be paid $40 a month, and in Cuba, Puerto Rico, the Hawaiian Islands, or the Philippines, $50 a month. If fewer than five nurses are serving in a hospital, the chief nurse does not receive increased pay; if five or more, but fewer than ten, are serving together, the chief nurse receives $10 a month additional; if ten or more are on duty together, the chief nurse receives $25 a month additional. A nurse is entitled to one ration in kind. She must provide herself with the prescribed uniform, and have it washed and ironed at her own expense. A nurse is entitled to receive medical attendance and care when she is sick, but only at the hands of medical officers and nurses of the army.

When a vacancy in the grade of chief nurses requires to be filled, it will be filled by promotion from the grade of nurses. The position of chief nurse is defined to be equivalent, so far as army conditions permit, to that of a superintendent of nurses in a civil hospital. Reserve nurses will be appointed from among those who have served acceptably as nurses for at least four months. Each reserve nurse will sign an agreement to enter upon active service wherever she may be required to do so, and to report by letter to the surgeon-general on the 1st of January and the 1st of July of each year, and at other times if required. She will wear the badge of an army nurse, but draw pay only when on duty. She will be dropped from the reserve list on reaching the age of forty-five years, or on discontinuing the practice of her profession for a period of five years, or for incapacity, or for any other good reason.

This scheme strikes us as, on the whole, very promising. We should like to see the nurses better paid, and we can not escape the conviction that in times of peace the remuneration offered by the government will hardly tempt into its service women of the class required, although in times of war our patriotic girls will throng to the soldiers’ aid. Doubtless the surgeon-general has done the best he could with the resources at his command, but we hope that congress will enable him to do better in the future. To be of enduring usefulness, a nursing corps should be permanent in its organization. Fortunately, permanence is substantially provided for in the establishment of a body of reserve nurses. To be a member of that body, privileged to wear the army badge, will be gratifying and inspiring to many a high-minded young woman. Would that the contract surgeons were adjudged entitled to some such recognition!

**THE BACILLUS PYOGENES CLOACINUS.**

The list of pathogenic micro-organisms is constantly growing. The latest organism of this sort that we have seen mentioned is one found in sewage and hence named by Dr. E. Klein (British Medical Journal, July 8th) the *Bacillus pyogenes cloacinus*. This micro-organism is found to be pathogenic when injected subcutaneously into guinea-pigs in minute doses. Ordinarily nothing more than a local abscess is the result, and then the bacilli are found only in the contents of the abscess. In many instances, however, the effect is diffused. Besides the abscess at the site of the injection, there are produced purulent peritonitis, with pyogenic membranes covering the liver, the spleen, and the kidneys; purulent pericarditis, with the pericardial sac filled with gross pus; and purulent pleurisy, with pyogenic membranes and solid lymph in the mediastinum and the lungs of a deep color and partially collapsed. When these distant lesions occur, the bacilli are found in the blood, particularly that of the heart and that of the spleen.

Minute doses injected into the peritoneal cavity of a guinea-pig lead to death in from twenty to twenty-four hours. On post-mortem examination, there are found purulent peritonitis, with pyogenic membranes on the liver, the spleen, the diaphragm, and the kidneys, and inflammation of the small intestine. Occasionally there are also pleural and pericardial exudates. In the mouse, small doses give rise to septicemia, but the bacillus has no pathogenic effect on rabbits. Presumably it is not yet known what its action is on the human subject; it is to be hoped that we never shall know.

Dr. Klein states that, culturally, his bacillus resembles to a certain extent Lößler and Schütz’s *Bacillus suscepticus*, but differs from it in its action on rodents, and is clearly distinct from Passet’s *Bacillus pyogenes fatalis* and from Bolton’s *Bacillus pyogenes soli*.

**A NOTABLE CASE OF STRYCNINE POISONING.**

In the British Medical Journal for July 1st Mr. Lancelet H. D. Hale, M. R. C. S. Eng., L. R. C. P. Lond., of Southsea, reports the case of a woman whom he was called to attend for an injury of the head produced by a fall. He found her unconscious, but it was
soon evident that her injury, a scalp wound, was not the cause of her symptoms. It was ascertained that she had swallowed by mistake six draçchs of tincture of nux vomica, containing three quarters of a grain of strychnine. She died in two hours, in the third paroxysm of general convulsions, after having thrice lost consciousness. The tube of the stomach pump could not be passed, owing to the attempt bringing on convulsive action. Amonorphine, in two subcutaneous injections of an eighth of a grain, failed to produce vomiting. The administration of chloroform, to enable Mr. Hale to introduce the stomach tube, caused such a severe syncope that he had to desist. The woman's pupils were widely dilated. The tincture swallowed was that of the new British Pharmacopoeia.

"GARDEN TRUCK" AND THE PREVALENCE OF CANCER.

Evert and anon somebody denounces the tomato as a breeder of cancer. Dr. Behla, of Luckau (Centralblatt für Bakteriologie und Infektionskrankheiten, xxiv, 21-24; Centralblatt für innere Medicin, July 8th), deals with the products of the garden more gencrously. He intimates in general terms that the people of Luckau, and especially of the suburban quarter called Kalau, owe the prevalence of cancer among them to their free consumption of fresh vegetables, and particularly of salads. He states that a myxomebe termed Plasmodiophora brassicae, which frequently gives rise to an epithelial swelling of the roots of the cabbage, is very abundant in Luckau.

AN ANTITOXINE TREATMENT OF ACUTE ALCOHOLISM.

If Dr. L. Marinali, of Naples (Giornale internazionale delle scienze mediche, 1898, No. 17; Centralblatt für innere Medicin, July 8, 1899), is correct, it is practicable to generate in the blood some substances which will serve as antitoxines to other than the "morbid" poisons. Such a substance he thinks he has formed by using progressively increasing doses of alcohol on the dog. The serum of such a dog he has used successfully in saving other dogs from the effects of doses of alcohol that would otherwise have proved fatal. If his experiments are corroborated, perhaps many an old drunkard may yet be made to serve a good purpose.

AN EXTREMIST IN CLEANLINESS.

It is almost always a layman who carries a matter of medical doctrine to the extreme. The Paris correspondent of the Lancet speaks of an amusing instance in that journal for July 8th. A Parisian traveling on a railway train refused to give his ticket into the hands of the railway company's official. When arraigned for having thus broken the law, he pleaded that he had been unwilling to put into his pocket a ticket which would be contaminated with microbes from the inspector's hands, they were so dirty! Nevertheless, he was fined a franc.

THE OVERCROWDING OF CARS.

The enormous overcrowding of cars in New York is a product of several factors. It is difficult to see, taking into consideration the rapidity with which the cars in our principal streets follow one another, how any material increase in car accommodation could be effected without reserving all the thoroughfares for the exclusive use of cars. But one avoidable cause of the overcrowding lies in the habit of the American people of crushing into a car to save themselves the trouble of walking, say four or five blocks. If the innumerable persons who have only four or five blocks to travel, and who presumably have no real occasion for any frantic hurry, would only walk the distance instead of "jumping on to a car," not only would there be much less overcrowding of public conveyances, but there would also result a diminution in dyspeptic and neurotic conditions, which are largely induced by the appalling and wholly unnecessary "hustling" in this and other cities. In nine cases out of ten "hustling" is only another form of laziness. The horse that makes the greatest showing does not always cover the greatest extent of ground in the shortest time.

THE REMOVAL OF GARBAGE.

Our present method of removal of garbage is a blot on the administration of the city of New York. Since we have practically no alleyways and back entrances, wherefrom regular dust bins could be emptied, we presume that the garbage can placed out on the sidewalks is inevitable. But why on earth can not these cans be emptied during the night, as the dust bins are emptied in European cities, instead of in the full light of day, to the intense annoyance of the public?

THE LUNGS OF A CITY.

A large city, like a human being, needs lungs. The lungs of a city are its open spaces where trees and shrubs inhale carbonic air and breathe out oxygen, thus reestablishing the balance for animal and vegetable nature. Beautiful as is Central Park, New York as a whole, is inadequately supplied with lungs. The city has extended enormously within the past few years, and that is an excuse for the errors of the past; but what shall we say about the future? Up Amsterdam Avenue are tracts of land on either side, even yet a primitive woodland. These lands are for sale, presumably for building purposes. Surely, before the fullness of city-dom reaches this district, the city should secure to itself park space, instead of waiting until the growth of the city in that direction renders it impossible without paying "fancy" prices in order to establish another Central Park. There is a "coefficient of life" possible for a given area of ground. As the animal increases, the vegetable decreases pro rata, and vice versa. New York has made many mistakes as regards its possible future development. Let it take care that it does not add yet one more, and that a very serious one, to the list! Let it secure patches of woodland wherever it can within its boundaries, and so get its necessary "lung power" cheap!

THE DESTRUCTION OF MOSQUITOS WITH KEROSENE.

An interesting experiment confirmatory of the efficacy of the plan proposed by Mr. Howard, of the United States Department of Agriculture, for exterminating those vexatious vehicles of malaria, mosquitoes, was recently made in England, as we learn from the British
Medical Journal for July 8th. Five drops of kerosene, added to a bucket of water estimated to contain between four and five hundred larvae, killed them all within an hour, and a teaspoonful killed within a few hours the many thousands contained in the water of a tank of nearly three hundred cubic feet capacity.

THE CENTRAL COLLEGE OF PHYSICIANS AND SURGEONS OF INDIANAPOLIS.

We regret to see it stated in one of the Indianapolis newspapers that there is in the faculty of this school a disagreement that has led to the resignation of some of the professors, and threatens to result in further resignations. Beyond the newspaper reports, we know nothing of the merits of the controversy; we simply deplore it on general principles.

RED CROSS PROTECTION NEEDED IN NEW YORK.

There has been reported in the newspapers an outrageous assault upon a physician for performing his professional duties to an injured non-union motorman during the recent strike in Brooklyn. The person of the physician has always been regarded by most people, even the most depraved, as inviolable when in the discharge of his duties, and it is significant of something radically wrong when men who profess to be respectable workingmen show themselves more devoid of humane instincts than the professional thieves, highwaymen, and murderers of old time. Such an act will rouse more bitterness and animosity against the race of "strikers" than all their other outrages put together.

THE RÖNTGEN RAYS IN THE TREATMENT OF SYCOsis AND FAVUS.

These diseases are to be added to the list of those in which the Röntgen rays have been thought to be of benefit. At a recent meeting of the Imperio-royal Society of Physicians of Vienna (Gazzette hebdomadaire de médecine et de chirurgie, June 15th) Dr. L. Freund showed three patients in whom he had cured both diseases (the account reads as if each patient had had them both) in from seven to thirteen sittings. The hair fell out and the cutaneous inflammation thereupon subsided. Dr. Kaposi did not believe, he said, that the cure would prove permanent in the case of favus, for the fungus was not so situated as to be affected by the rays.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the week ending July 22, 1899:

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 15 to July 22, 1899:

| AGRAMONT, ALESTIDE, Acting Assistant Surgeon, United States Army, will report to the medical officer in charge of the yellow-fever hospital, Santiago Bay, for temporary duty as bacteriologist. |
| BACHUR, DALLAS, Colonel and Assistant Surgeon-General, United States Army, is detailed as a member |
of the board of medical officers appointed to meet in Washington, by S. O. 61, vice Hall, William R., Major and Surgeon, United States Army, relieved.

Balch, Lewis, Major and Surgeon, United States Volunteers, will proceed to Amaro to examine its suitability for a camp site, in case circumstances should render it necessary to remove the troops from Sagua Barracks.

Bowen, William, Captain and Assistant Surgeon, United States Volunteers, is assigned to the Twenty-seventh Infantry, United States Volunteers, and will proceed to Camp Meade, Middleport, Pennsylvania.

Bratton, Thomas S., Captain and Assistant Surgeon, will proceed to Camp Meade to accompany the Nineteenth Infantry to Manila.

Ebert, R. G., Major and Surgeon, United States Army, will make the examination and report, and supervise the completion of volunteers to be mustered out at Vancouver Barracks, Washington.

Fisher, Henry C., Captain and Assistant Surgeon, United States Army, will report to the surgeon in charge of the First Reserve Hospital for duty.

Griswold, Richard S., First Lieutenant and Assistant Surgeon, United States Volunteers, is assigned to the Twenty-sixth Infantry, United States Volunteers, and will proceed to Plattsburg Barracks, New York.

Kean, Jefferson R., Major and Surgeon, United States Volunteers, is detailed as a member of the board of officers convened by Par. 1, S. O. 114, vice Brown, Ira C., Major and Surgeon, United States Volunteers, relieved on account of sickness.

Kendall, William P., Major and Surgeon, United States Volunteers, in addition to his other duties, is assigned to temporary duty to organize wards in the Cuartel de Infanteria, 73, which wards will be supplementary to the First and Second Reserve Hospitals.

Summerrall, W. B., Acting Assistant Surgeon, United States Army, will report to the officer in charge of the military hospital at Matanzas, Cuba, for duty.

The following-named medical officers are detailed to represent the Medical Department of the Army at the eighth annual meeting of the Association of Military Surgeons of the United States, to meet in Kansas City, Missouri, from September 27 to September 29, 1899: Alden, Charles H., Colonel and Assistant Surgeon-General, United States Army; Torney, George H., Major and Surgeon, United States Army; Powell, Junius L., Major and Surgeon, United States Army.

The following-named medical officers of the United States Army will proceed to the Philippine Islands on the transport City of Para: Flagg, C. E. B., Captain and Assistant Surgeon; Fauntleroy, P. C., First Lieutenant and Assistant Surgeon; Dutcher, Basil H., First Lieutenant and Assistant Surgeon; Dean, Elmer A., First Lieutenant and Assistant Surgeon; Grekler, H. S., First Lieutenant and Assistant Surgeon; Rash, Otway W., First Lieutenant and Assistant Surgeon; De Kraft, Chase, Acting Assistant Surgeon; Schultz, Ernest C., Acting Assistant Surgeon; Le Hardy, Julius C., Acting Assistant Surgeon; Van Deusen, James, Acting Assistant Surgeon; Harris, Stevens T., Acting Assistant Surgeon; Robbins, Robert F., Acting Assistant Surgeon; Seaman, Gilbert E., Acting Assistant Surgeon; Garlington, J. C., Acting Assistant Surgeon.

The following transfers and assignments of members of the Medical Department are announced: Darling, J. B., Acting Assistant Surgeon, United States Army, will report to the commanding officer, Third United States Infantry, for duty with one of the battalions of that regiment in the field; Hartnett, Eugene H., First Lieutenant and Assistant Surgeon, United States Army, will report to the commanding officer, Twenty-second United States Infantry, for duty with that regiment, relieving Kulp, John S., Captain and Assistant Surgeon, United States Army, who will report to the surgeon in charge of the First Reserve Hospital for duty in connection with the supplementary wards now being established in the Cuartel de Infanteria, 73; Edie, Guy L., Major and Brigade Surgeon, United States Volunteers, will report to the commanding general, Second Division, Eighth Army Corps, for duty in charge of the field hospital of that division, relieving Adams, F. J., Major and Surgeon, First Montana Volunteer Infantry; Banta, William P., Acting Assistant Surgeon, United States Army, will report to the commanding officer, First South Dakota Volunteer Infantry.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending July 20, 1899:

Ballache, Preston H., Surgeon. To proceed to New York for special temporary duty in the Purveying Depot.

Banks, C. E., Surgeon. Relieved from duty at Washington, D. C., and detailed as Medical Purveyor of the service at New York.

Geddings, H. D., Passed Assistant Surgeon. To proceed to New York for special temporary duty.

Rosenau, M. J., Passed Assistant Surgeon. Detailed as inspecting quarantine officer for the Island of Cuba.

Freiks, L. D., Assistant Surgeon. To proceed to the Brunswick Quarantine Station, Brunswick, Georgia, for special temporary duty.

McAdam, W. R., Assistant Surgeon. Granted seven days' extension of leave of absence.

Richardson, T. F., Assistant Surgeon. Relieved from duty at the Immigration Depot, New York, and directed to proceed to Cienfuegos, Cuba, for temporary duty.

Thornbury, F. J., Assistant Surgeon. To proceed to Point Pleasant, New Jersey, for special temporary duty.

Burford, R. E. L., Sanitary Inspector. Granted leave of absence for seven days.

Appointment.

Weeks, Alan, of Michigan, to be Acting Assistant Surgeon, United States Marine-Hospital Service, for duty at the port of Chicago, Illinois.

Changes of Address.—Dr. J. P. Chartland, from Cohoes, New York, to No. 135 Third Street, Troy, New York; Dr. F. Phelan, to No. 131 Third Street, Troy, New York; Dr. Waldo H. Sanford, from Brewster, New York, to Saratoga Springs, New York.
DEATHS.—LETTERS TO THE EDITOR.

[New York Med. Jour.,]

Births, Marriages, and Deaths.

**Died.**

**Chamberlain.**—In Jamaica Plain, Massachusetts, on Tuesday, July 18th, Dr. Cyrus N. Chamberlain, of Andover, Massachusetts, in the seventieth year of his age.

**Lyons.**—In Boston, on Monday, July 17th, Christopher P. Lyons, infant son of Dr. Christopher P. Lyons.

**Sturgis.**—In Boston, on Monday, July 17th, Dr. Russell Sturgis, Jr.

**Wood.**—In Clinton, Louisiana, on Monday, July 17th, Dr. Frederick D. Wood, in the forty-sixth year of his age.

Letters to the Editor.

A CASE OF QUADRUPLETs.

Union Mills, Indiana, July 7, 1899.

To the Editor of the New York Medical Journal:

Sir: If the rarity of four babies at one birth makes the following care worthy of mention, readers of the Journal are welcome to the trouble it costs me to write it.

On June 25, 1899, Mr. James P. came to my office for medicine for his wife, stating that she was about six months pregnant, and for two days had been very nervous and having pain in the back. I gave him a small bottle of fluid extract of black haw, with directions for his wife to take a teaspoonful in hot water every three hours; also some tablets of triple bromides, seven grains and a half each, one to be taken every four hours. I instructed him to have her remain in bed for a day or two and report to me the following day.

The next day I was called to the home of her mother, to which she had come on a visit in the morning. I arrived there a few minutes after three. Immediately her mother called my attention to a protruding cord. I hastily washed my hands, and in a very few minutes extracted, feet foremost, a living female child which weighed twenty-nine ounces. Only a glance at the abdomen was needed to tell me I was not yet through. A little before five o'clock another female child, which weighed twenty-six ounces, was extracted feet foremost. This child gasped faintly—only enough to show that life was present. The mother claimed my attention for a few minutes, and when I turned to the child it was dead. I made some efforts to resuscitate it, but to no avail. Upon further examination of the mother, I found a head presenting. Later the occupant was found to be to the right and posteriorly. This child was coming slowly and I took time to go down to the hotel (one block away) and eat my supper. At a little before seven this child was born, a dead female of twenty-six ounces. Upon further examination I found a shoulder presenting. I tried to manipulate it so as to bring the head down first, but could not; the child was easily turned and the feet were brought down, and the fourth female child, weighing twenty-three ounces, was extracted dead. The first child lived about forty-three hours and then died, in spite of cotton, colli-vir oil, and an extemporized incubator. During the labor the mother was given eighteen grains of quinine; no other medication was employed save two hypodermics of ergot, which were given to stop a hemorrhage which followed the expulsion of the placenta.

The birth was a premature one; I pronounced the gestation to be advanced between six and seven months. The nails were just beginning to show on the great toes and the fingers, the hair on the head was beginning to show, and the eyebrows were nearly visible.

On examining the woman the first time I found the bag of waters broken, but with each of the succeeding fetuses I had to rupture the membranes, which were very strong. The placenta, which I did not weigh, was not large, and the cords were inserted probably two inches apart.

The peculiar feature is four babies, all of the same sex and so equally developed, their respective weights being twenty-nine, twenty-six, twenty-six, and twenty-three ounces. The mother is only eighteen years and six months old, and I never attended a confinement where the mother had an easier labor. Of course the children were small, but I attributed the lack of suffering partly to the black haw and bromides given in the fore part of the day.

C. V. Leedy, M. D.

TETANUS AND INFECTED CARTRIDGES.

Utica, N. Y., July 16, 1899.

To the Editor of the New York Medical Journal:

Sir: I notice by the lay press the unusual number of cases of tetanus following gunshot wounds inflicted by blank cartridges. It seems to me that the infection is primary, due to the wad or packing, and not a secondary infection resulting from dirt. In the summer of 1881 or 1882 there were numerous cases of tetanus following the same injuries and inflicted by the same weapon, the blank cartridge and toy pistol. The wad of the cartridge is earth and paper. It would be very interesting to trace the source of the earth used in their manufacture.

I am of the opinion that it comes from some place unusually infected with tetanus, like certain spots on Long Island, for instance.

It could be demonstrated by cultures from the wads by Kita-sato’s method. Check experiments with earth from the original source would complete the chain of evidence, provided the manufacturers would say where they got it. A scientific investigation would do much to put a stop to the crude and ignorant deduction that gunshot wounds of the palm are more prone to tetanus than other wounds in other localities, and that the rusty nail is largely to blame.

I hope there will be some work done in accordance with this suggestion. William Stump, A. M., M. D.

A NEW PREPARATION OF QUININE.

Amherst, Ga., July 8, 1899.

To the Editor of the New York Medical Journal:

Sir: It is well, I think, to inform the profession concerning an article of marked merit when it can be honestly done; hence this letter.

I have given quinolin (a tasteless powder of quinine sulphate with olive oil) a thorough trial with a number of patients who have been suffering with malarial fever, and in every instance the results have been highly satisfactory.

I find a great many cases where sulphate of quinine

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By ARTHUR N. TAYLOR, LL. B.

XXIX.

CIVIL MALPRACTICE, INCLUDING GENERAL LIABILITY OF PHYSICIAN TO PATIENT.

(Continued from page 156.)

Failure to give Proper Instructions.—Nor does the physician’s liability necessarily end when he has treated the patient with all due skill and care, exercising proper judgment and using the most approved methods of treatment.

If the character of the injury or disease is such that any particular method of nursing is necessary to avoid an aggravation of the injury or prevent a relapse, or if the patient’s welfare requires that he shall observe certain rules or practices, or shall avoid any particular indulgence, the physician is bound to inform the nurse or patient, or both, as the case may require, of the condition he wishes to avoid, and give them proper instructions as to the care and treatment best calculated to conduce to a cure. In the case of Carpenter vs. Blake the court said: “If, in case of dislocation of the elbow joint, it is enough for the physician to replace the bones, and to put the arm on a pillow, with the part below the joint at a right angle with that above it, and direct the application of cold water, it would seem to be proper, if not necessary, that the attending surgeon should inform the patient, or those having charge of him or her, of the necessity of maintaining that position; and if there is a tendency in the limb to become straight, or if in consequence of the severity of the injury to the ligaments about the joint there is great pain, which renders the patient nervous and restless, thus increasing the tendency of relaxation, or to straighten, and, as a consequence, to stiffen the joint, the danger should be disclosed, to the end that all proper precaution may be taken to prevent it. It is insisted that these dangers were imminent, and yet no word was given. This was, in my judgment, culpable negligence; much of the suffering the plaintiff has undergone, and much of the loss she has sustained, might have been prevented had the defendant done what it was clearly his duty to do, if he knew the consequences which might result from redislocating the joint or straightening the arm.”

In the case of Beck vs. The German Klinik et al., the evidence showed that the plaintiff, who had broken his leg, employed the defendants, viz., the German Klinik, an infirmary, hospital, and certain physicians and surgeons members of that concern, to treat him; that the methods and appliances which were used in the treatment of the case were such as were used and approved of by physicians who were possessed of and who exercised at least the average skill of the medical profession as a body at that time; and that the treatment seemed to have been proper and skillful, and the leg, when the splints and bandages were removed, appeared all right. The evidence also showed that after the gypsum bandages, used to keep the bones in place, were removed, the defendants directed the plaintiff to use his limb and to walk with crutches, but that they gave him no further directions as to the manner or extent of such use. The evidence further showed, or tended to show, that the broken bone had not well united, either because of improper treatment or because of its diseased condition, and that when the bandages were removed, or soon thereafter, the limb at the wounded part was crooked, and that it became necessary to perform an amputation. An expert witness testified upon examination of the limb after amputation, that there was a diseased condition of the bone which might have been caused by “a splinter or a muscle getting between the bones; and in that case walking would irritate and produce a tendency to disease.” He further said: “I would instruct my patient not to walk on a leg I found not united.” “The least weight of the foot, after patient commenced walking, would tend to separate at the top” (pointing to a portion of the bone, having the amputated limb before him). “If the bone, when set, confined in its apparatus for eight weeks, came out in that crooked condition or form, then the tendency of the use of that limb in walking would insure its efficiency and would induce disease.” The court, in commenting upon the legal effect of the evidence above given, said: “The jury were authorized to find that plaintiff had no correct instructions as to the proper care and use of his wounded leg; and that he had wrong instructions which directed him to use his leg; that the diseased condition was caused or aggravated by the use of the leg, which the defendants directed, and that with proper instructions, which we will presume plaintiff would have followed, his leg would have been saved, or at least the disease of the bone would have been ameliorated and he would have escaped much suffering.” “Defendants may have exercised proper care and used proper skill in all things, yet, under the law of the case, if they omitted to give plaintiff proper instructions for the care and use of his wounded leg they were rightly held liable by the jury. As we have said, the jury were authorized to find for plaintiff under the evidence on the ground of defendants’ negligence by omission to discharge their duty to instruct plaintiff as to the care and use of his injured leg.”

In a recent Ohio case the trial judge, in instruct-
ing the jury regarding this duty of the physician, stated the law very clearly; he said: "It is the duty of the surgeon, when he takes charge of a case, such as a broken femur bone, to give his patient all necessary and proper instruction as to what care and attention the patient should give his broken limb in the absence of the surgeon, and the caution to be used in the use of the limb before it is entirely healed."

The case in which this instruction of law was required by the facts at issue happened to be one in which the patient had suffered from a fracture of the femur—hence the narrowness of its scope; the law applies equally well, however, whether the patient be suffering from a fractured femur or a fractured rib, or whether the affection be typhoid fever or mumps. Proper and necessary instructions are in all cases required by the law.

**Liability for Improperly Discontinuing Attendance.**

—In an earlier chapter of this work the implied contract of the physician that he will continue his attendance upon the patient so long as his condition shall require it has been considered. Should a physician fail to pay due regard to this obligation and cease his attendance at a time when by the exercise of an honest and properly educated judgment he might have determined that his services were still required, he will be liable to an action for damages resulting therefrom.*

Justice Pryor, in an instruction to the jury, expressed the law very clearly and forcibly. He said: "The defendant was called to treat the plaintiff for a miscarriage. He visited her the day of her misfortune and the two succeeding days; but he never came afterward. It is not denied that when he ceased his visits she was not cured of her malady. His retainer was for no definite period. Upon this state of facts the question is, Did the defendant violate his duty to the plaintiff by his abandonment of her? When a physician engages, as here, to attend a patient without limitation of time, he can not cease his visits except, first, with the consent of the patient; or, secondly, upon giving the patient timely notice, so that he may employ another doctor; or, thirdly, when the condition of the patient is such as no longer to require medical treatment, and of that condition the physician must judge at his peril. Here it is not shown that the plaintiff was no longer in need of medical attention; so that the defendant had no right to discontinue his attendance, unless either the plaintiff consented or he gave her proper notice; and if he left her without such consent or such notice he was guilty of grave professional negligence. The defendant swears that at his last visit he notified the plaintiff that he was going out of town, and indicated to her a physician who would attend her in his stead. If this statement be true, the defendant's absence is excused, and you must exonerate him from this imputation of neglect. But the defendant's story is denied by the plaintiff's witnesses, and their testimony tends to prove that he abandoned her without leave and without notice." †

Upon the law governing this liability there seems to be no question or disagreement, it is upon the facts that the parties conflict, the defendant usually testifying that he notified the patient of his inability to render further services; the patient, on the other hand, testifying that no such notice was given.*

In the cases considered above the services of the physicians were rendered at the patients' homes, but the principle of law controlling is the same when the services are rendered by the physician at his office. Of course, if the patient comes to the office of a physician from whom he has received proper treatment and then fails to return for further treatment, in consequence of which he suffers injury, the physician is not liable to an action for such injury. † But if a physician who is receiving and treating a patient at his office fails through his own fault or neglect to meet the patient at the usual or proper time and place, whereby the patient suffers injury, then the physician is liable in damages to the amount of the injury so sustained.

(To be continued.)

**Pith of Current Literature.**

**Aspirin, a New Salicyl Preparation.**—Dr. Karl Wittmayer, of Halle (Heitkunde, April; Deutsche Medicinal-Zeitung, May 15th), describes aspirin as a compound of acetic and salicylic acids, forming white crystalline needles readily soluble in ordinary solvents. He has given it in doses of fifteen grains four or five times a day in all affections in which the salicyl preparations are employed, and has found it equally effective with sodium salicylate and thus far free from any unpleasant effect on the heart or stomach. It was astonishing, he says, how well the appetite was sustained even in patients who had to take aspirin for a long time. Upon this statement the Zeitzung's writer comments as follows: It works slowly, then, in many cases.

**Extract of Corpora Lutea as a Medicine.**—The Paris correspondent of the Lancet for July 15th says that at the meeting of the Society of Biology, held on June 24th, Monsieur A. Lebreton laid before the society the results of his researches into treatment by means of extract of the corpus luteum. In an inaugural thesis M. Lebreton had already pointed out that by their histological structure it was evident that the corpora lutea were really ductless glands and that the benefits of treatment by ovarian extract depended mainly upon the principles contained in the corpora lutea. As a means of experimental verification of his theory he had some capsules made, each containing 0.05 of a centigramme of pure corpus luteum. These he administered to three patients suffering from the following symptoms: flushes of heat, buzzing in the ears, sweats, feelings of "sinking" sometimes going on very nearly to fainting, nightmares, breathlessness, palpitations, and digestive troubles—in a word, all the symptoms due to "ovarian insufficiency." Two capsules per diem were given before the principal meals of the day. The drug acted promptly with notable success and there were no ill effects noticed. M. Lebreton is now pursuing his researches into the therapeutics of the corpus luteum

as regards the various troubles of pregnancy—notably vomiting. He has already met with two cases in which the results were conclusive, but reserves publication until he has a larger number of cases upon which to report.

A Peculiar Result of Attempted Self-induced Abortion.—In the Surgical Section of the Ontario (Canada) Medical Association, Dr. Harrison, of Selkirk (Canada Lancet, July), reported the case of a woman with a considerable family, who, having become pregnant again two months and a half, was advised by a neighbor to produce an abortion, as it was a very easy thing to do and no trouble arose other than from an ordinary monthly sickness. A glass stylet penholder was passed blunt end foremost, but slipped from the woman’s grasp and was lost to her touch. On examination, Dr. Harrison could find no rent or tear of any kind either in the vaginal walls or in the walls of the uterus. Even after putting the woman under chloroform the stylet could not be found. The woman was most positive that it was there, and that it had been passed blunt end foremost. An exploratory abdominal operation was performed, and the stylet was found in the region of the spleen with the point almost impinging upon the diaphragm where the heart lies on that muscle. The woman recovered with nothing worse than a stitch abscess.

"Prickly Heat."—This troublesome affection, especially incident to tropical climates, has exhausted the resources of many physicians. Dr. Frederick Pearse, of Bombay (Journal of Tropical Medicine, June) gives the following accurate description of it, and makes some suggestive remarks on the rationale of treatment. He says that it consists of an eruption of extremely minute red papules, which appear at first as red points, and then become raised into tiny hillocks. The numerous minute, closely set, and slightly inflamed papules produce an appearance not unlike that caused by an irritant liniment. The small papules, essentially discrete, become in severe cases almost confluent, and some of them develop an opacity at their apices. By pressure or rubbing, a very minute quantity of a creamy material can then be expelled. The rash is extremely irritable, and attended with severe pricking and tingling sensations. A few spots resembling acne are generally also to be observed, and occasionally a large-sized inflamed acne spot gives the appearance of a boil. The little vesicles at the apices of the papules do not contain clear fluid, nor, beyond the most minute quantity of a creamy material, is there anything like suppuration. He regards this as pent-up sebaceous matter. In the same way the acne spots at first contain sebum, although they may subsequently inflame, and ultimately form and discharge pus.

Although anything which excites perspiration "brings up" the rash and aggravates the symptoms, the disease does not appear to be directly connected with the sweat glands. It is not a form of malaria, as some assert, but a seborrhoea. There are seldom any sudamina vesicles such as are so frequent in rheumatic and other perspiring diseases, and in the excessive perspirations of active exercise. The rash of prickly heat is distinctly limited to those parts of the skin containing sebaceous glands, and will be found, for example, to show a sharp margin between the back of the hand and the palm, where the hairs and sebaceous glands suddenly leave off. It seems to have a special predilection for those parts where the hairs are soft and downy. The front of the chest and abdomen, the shoulders and back and the arms, are the most frequently and most severely affected regions. It occurs also on the face and legs, but not generally to the same degree. It is not a matter of clothing, because it occurs on the backs of the hands and on the face, and on the bare legs of children. A very fine desquamation often follows from those parts which have been most severely affected. The irritation is sometimes so intense that sleep is seriously disturbed, and the restlessness produced in the daytime is to dedicate persons very wearying. There is no definite course. It may last for a few days, or it may go on for months. It varies from day to day, and a short spell of cool weather will sometimes clear it temporarily almost all away.

While excessive perspiration will very quickly produce sudamina, this is not the case in prickly heat. Many days’ experience of hot weather is required before the rash develops, and sudamina are seldom observed. It seems that the prolonged sweating excites at the same time the activity of the sebaceous glands. Certain of these smaller glands, not being accustomed to such activity, get their ducts choked up, and are apt to become inflamed. It is the obstruction of the ducts of the larger sebaceous glands which causes acne—those glands which are generally associated with medium-sized hairs, while the vast number of smaller glands probably connected with the downy hairs are affected in seborrhoea. Dr. Pearse looks upon prickly heat as an acute seborrhoea maintained in a more or less active state by the continued irritation of excessive perspiration.

Treatment.—In the way of prevention it must be remembered that as the complaint is so intimately associated with excessive perspiration, anything which tends to cause this must be avoided. Hot drinks are especially bad, but even iced drinks will excite perspiration in a heated atmosphere. A large quantity of any drink is injurious. Close, ill-ventilated rooms, too much clothing, and exercise will, of course, naturally excite perspiration. These matters must therefore be attended to. The clothing should be as scanty as possible, and not made of wool or silk. Open-wave cotton material is the most comfortable. The bed must not be luxurious with soft mattresses and warm pillows, but such as will offer rapid conduction away of the body heat. A punkah at night seems necessary for many people—it is certainly a great comfort. Excessive bathing, especially with the use of soap, seems to aggravate it. It is not sufficiently borne in mind that soap removes sebaceous matter from the surface of the skin; that the skin, thus freed from its natural oil, tends to become dry, rough, and hard; that the sebaceous glands are thus unduly stimulated to produce more secretion, while at the same time the excessive perspiration is also irritating them to lubricate the surface. The removal of the natural grease of the skin under these circumstances is distinctly disadvantageous, and bathing should be performed with plain water. Soap is only required when bathing is neglected.

Curative treatment follows on these lines. The body should be anointed with oil for the purpose of protecting it against the irritation of the exuded sweat. It also keeps the skin soft. The best preparation Dr. Pearse considers to be a mixture of almond oil and lanolin in the proportion, say, of 8 to 1, and scented according to fancy. The body should be anointed with this
night and morning, and gentle massage of the skin used at the same time relieves the distressing symptoms. The skin is sometimes so excessively tender that anything like rubbing must be avoided.

The domestic remedies of bran or ammonia in the bath he finds of little value, while lemon juice smeared over the skin is of doubtful benefit. Lotions of Goulard water or astringents afford but very temporary relief, and the same may be said of the numerous antiseptic dusting powders. The excessive perspiration is liable to cause eczema intertrigo, so that drying powders for the axilie, under large mammae and between the skin folds of fat people, are useful. On the prickly heat itself they seem to have little control. Temporary relief can be obtained by lotions of carbolic acid, of menthol, and of many other drugs, but lasting improvement is secured by the use of oil. It need hardly be said that vaseline is not the equivalent of oil for this purpose. Lanolin, however, when freely used (and it must be very freely used) and when combined with a pleasant oil, he regards the most successful application.

The Pulse in Pneumonia.—M. Carrière, of Lille (Progrès médical, June 24th), stated at a recent meeting of the Société médicale des hôpitaux that the pulse in the evening frequently takes on in pneumonia the hesitating character shown on the sphygmograph by a broken ascending line. This phenomenon, he says, is easily perceptible to the touch in severe cases of pneumonia. Its prognosis is very grave, it coincides with feeble arterial tension and cardiac failure due to myocarditis. Of six patients in whom this phenomenon was noted, five died.

The Danger of Peroxide of Hydrogen in Surgery.—Dr. George W. Spencer (Therapeutic Gazette, July 15th) points out that useful as peroxide of hydrogen is in surgery, it is not altogether innocuous, and, like most things, has its dangers. He records a case of carcinoma of the breast on which he operated and which did well till the patient became an out patient. A sinus was injected with peroxide of hydrogen to keep it clean, and it was noticed that at each injection a larger quantity of the fluid was needed, till, finally, a swelling about half the size of an egg appeared on injection, which could be heard cracking and felt to crepitate. Pressure on the swelling caused the escape of bubbles of gas. Inflammation and suppuration of the entire area followed. Dr. Spencer says that he has no doubt that in this case the expansive force of the peroxide made new channels and forced and deposited pyogenic organisms into these channels from the original two-inch sinus. After incising at several points, draining, and discontinuing the peroxide, the patient made a good recovery. Dr. Spencer records three other cases, occurring while he was a resident at the Jefferson Hospital, in which stitch abscesses were injected with peroxide of hydrogen, the injection being followed by cellular inflammation with emphysema—the gas eliminated by the peroxide apparently carrying infection with it. The injection of peroxide of hydrogen appears also to have resulted in some cases in the infection of the intermuscular planes of cellular tissue. Dr. Spencer quotes several previous communications on this subject, which is not altogether new, but it is worthy of note by the practitioners in view of the wide use of this agent and the widespread belief in its perfect innocuousness. It is not intended to discourage its use, but to warn the practitioner of dangers that may arise, so that he may attribute them to the right cause should they occur to him.

The Control by Arsenic of the III Effects of Thyroid Extract.—Mably (Revue de thérapeutique, May 1st; Medical News, July 8th) hopes that he has found in arsenic a means of preventing the ill effects of thyroid extract, which are produced in some patients by this drug. The increased use of the thyroid gland, not only for myxedema, but for obesity, goitre, certain skin diseases, and in general for malnutrition, makes it important that there should be some means of controlling the vertigo, palpitation, dyspnoea, anxiety, etc., from which patients who are particularly sensitive suffer. The writer observed that these symptoms disappeared in one of his patients when he was taking Fowler's solution and reappeared when she stopped the arsenic. From two to twelve drops of Fowler's solution at a dose were found to be sufficient to prevent any unpleasant symptoms even when taking twelve grains a day. Two other patients took arsenic with thyroid extract with happy results, and the arsenic did not weaken, apparently, the force of the thyroid extract.

The Position of the Gravid Uterus at the Onset of Labor.—Dr. Alexander Maclean (Glasgow Medical Journal, July) concludes a paper on this subject as follows: "1. Right flexion with right rotation is by far the commonest deviation. No case of the converse was met with. 2. Flexion is caused by purely mechanical conditions, and it will tend to produce rotation to the same side. 3. Flexion has no relationship with presentation or position of the fetus. 4. Rotation is due to laxness of the uterine ligaments, and possibly to an irregular contraction, but not to an irregular arrangement of the muscular fibres. It may replace latero-flexion as an attempt at accommodation. One case showed in the space of three days, first symmetry, then rotation to the right, and finally rotation to the left. 5. Only two cases of flexion without rotation occurred, and these were complicated by contraction of the uterus. An absolutely symmetrically placed uterus is more common in primiparae, but one medianly placed, if accompanied by rotation, is commoner in multiparae."

Wound Infection as a Causative Factor in Puerperal Insanity.—Dr. A. T. Hobbs (American Journal of Obstetrics, July), in a paper on this subject, says that during the past four years and a half they have at the London (Ontario) Asylum endeavored to secure from the friends of the incoming female patient and the family physician an account of the previous diseases (if any) the patient has suffered from, and especially all the facts concerning the number of children and of the different puerperiums. Having this information, they are then able to decide whether or not to make a gynaecological examination of the insane woman. They have to date examined a hundred and eighty-seven women—recent admissions and chronic patients—and found distinct pathological lesions in a hundred and sixty-three. Of the one hundred and sixty-three there were no less than eighty who had inflammatory lesions of the pelvic organs that were, so far as they could judge, brought about by septic invasion at the time of a puerperium. All of these eighty women had marked subinvolution of chronic metritis, and forty-two had complicating diseased cervixes. Some thirty-three had retrodisplaced uterus, and nineteen had more or less serious lacerated perinea. In addition, eleven had inflammatory tubal
or ovarian disease, three had fibroid tumors, and one a
deep rectal fistula.

Subsequent to suitable surgical treatment of these
eighty cases they had return to physical health in
nearly all, and thirty-six, or forty-five per cent., recov-
ered mentally, and twenty, or twenty-five per cent., had
mental improvement, while the mental condition of the
remaining twenty-four, or thirty per cent., remained
stationary.

From this, says the author, it is evident that if sep-
tic infection is mainly responsible for the production
of inflammatory conditions of the pelvic organs occur-
rning during the puerperium, and in so large a percent-
age of cases mental recovery and improvement succeed-
ed the removal of these lesions, it strongly emphasizes
how important a factor the micro-organism is directly
or indirectly as the cause of many a case of mental
alienation. Moreover, it teaches these valuable les-
sons, that too great care can not be adopted by the
accoucheur in conducting a female through the really
dangerous period of the puerperium and protecting her
from sepsis, and, to those having the care of the female
insane, it teaches that to remove the inflammatory
lesions of the pelvic organism, when found, is to open up
a possible avenue of escape from mental thraldom
for many of these unfortunate exiles of humanity.

**Book Notices.**

*Beiträge zur Augenheilkunde* in Gemeinschaft mit Pro-
*fessor Dr. E. Fuchs,* in Wien; Professor Dr. O.
*Haab,* in Zürich; Professor Dr. A. *Vossius,* in Gies-
*sen. Herausgegeben von Professor Dr. R. Deutsch-
mann,* in Hamburg. Heft 31–40. Hamburg und
Leipzig: Leopold Voss, 1899.

The last ten parts published of Deutschmann's
*Beiträge* contain much that is interesting. They pre-
sent twenty-eight articles and complete the fourth vol-
ume. The papers of special interest and importance are
three in number—viz.: one by Ammann, on retinal
hemorrhages in diseased conditions of the blood and
blood-vessels; one by Haab and Sidler-Huguenin, on the
final results in the treatment of glaucoma; and a very
lengthy and elaborate paper by Deutschmann on his
method of treatment of detached retina. Ammann's
paper is a discussion of the various kinds of retinal
hemorrhage, with special reference to the aetiology and
pathology. It is illustrated by cases and post-mortem
examinations, and covers seventy pages.

The paper on the after-results in glaucoma is an
extremely interesting one, being based on careful and
long-continued observation of seventy-six private pa-
tients of Professor Haab's. In the tables that accom-
pany it it may be seen that in acute inflammatory glau-
coma iridectomy effects a complete cure in more than
half the cases, and improves the vision in all. The prog-
nosis in chronic inflammatory glaucoma is much bet-
ter than the author had before supposed. They prefer
iridectomy to sclerotomy in glaucoma simplex, and con-
sider that a favorable prognosis may be given, which is
a much more optimistic view than that held by most
modern authors.

Deutschmann's paper on his own method of treat-
ment of detachment of the retina covers 226 pages and
contains the detailed histories of a mass of cases which
make very heavy though useful reading.

*Atlas of the External Diseases of the Eye;* including a
Brief Treatise on the Pathology and Treatment.
By Professor Dr. O. Haab, of Zürich. Authorized
Translation from the German. Edited by C. E. de
Schweinitz, A.M., M.D., Professor of Ophthal-
mology in the Jefferson Medical College, Philadel-
phia, etc. With Seventy-six Colored Plates and Six
Pp. 7 to 228.

This volume is the counterpart of the author's *Atlas
of Ophthalmoscopy,* and is among the best of its kind.
But the author had a much more difficult task to per-
form than in the former volume, on the internal dis-
cases of the eye, for, as he himself says, there are many
appearances which can not be satisfactorily reproduced
on paper. Each chapter is accompanied by a brief treat-
tise on the pathology and treatment of the diseases con-
sidered in it, which contains all the essential points.
The first chapter is on functional testing, and it is fol-
lowed by chapters on the various diseases seen in a large
ophthalmic clinic. Many of the colored plates are ex-
ceedingly well done. Where deficiencies occur, they are
due to failure to secure the necessary clinical material.

*An Essay on the Nature and the Consequences of
Anomalies of Refraction.* By F. C. *Donders,* M. D.,
Late Professor of Physiology and Ophthalmology in the
University of Utrecht. Revised and edited by
CHARLES A. OLIVER, A.M., M. D. (Univ. Pa.), one
of the Ophthalmic Surgeons to the Philadelphia
Hospital, etc. With Portrait and other Illustra-
tions. Philadelphia: P. Blakiston's Son & Co.,

The American editor has presented to the ophthal-
mic world the complete series of Donder's aphorisms,
exactly as they appeared in the original work. There
are one hundred and thirty-nine of them, and it is inter-
esting to note to what a very slight extent these aphor-
isms have undergone correction or alteration in the
thirty years that have elapsed since their publication.
All this is an additional proof of how far in advance of
his fellows the late Professor Donders was. The bro-
dure is divided into seven sections, and closes with a
brief bibliography.

*Retinoscopy (or Shadow Test) in the Determination of
Refraction at One Metre Distance with the Plane Mirror.*
By JAMES THORINGTON, M. D., Adjunct
Professor of Diseases of the Eye in the Philadelphia
Polyclinic and College for Graduates in Medicine,
etc. Third Edition, revised and enlarged. Forty-
three Illustrations, Twelve of which are Colored.
Pp. xviii–19 to 86. [Price, $1.]

The first edition of this little book was published in
1897, and met with a gratifying success. The present
edition contains forty-three illustrations, twelve of
which are colored. It is not intended to take the place
of the more elaborate works on skiascopy, but is mainly
intended for undergraduate and post-graduate students.
There are six chapters and a good index. The success
of the previous editions has proved it to be a useful lit-
tle work.

Any student or practitioner of medicine who wishes to refresh his memory with medical aphorisms which can be remembered if read but once, should possess a copy of this small volume.

This is an extremely useful and practical guide to the methods used in the examination of the nose and throat, and it is unfortunate that it is accessible only to those who read German.

BOOKS, ETC., RECEIVED.

Selected Papers on Stone, Prostate, and other Urinary Disorders. By Reginald Harrison, F. R. C. S., Formerly Senior to the Liverpool Royal Infirmary and Lecturer on Clinical Surgery in the Victoria University, etc. Philadelphia: P. Blakiston's Son & Co., 1899. Pp. 190. [Price, $1.75.]

Transactions of the Louisiana State Medical Society, at its Nineteenth Annual Session, held in New Orleans, May 10, 11, and 12, 1898.

Yesterday and To-Day. By Francis J. Shepherd, M. D., of Montreal. [Reprinted from the Montreal Medical Journal.]

A Contribution to the Study of Bright's Disease, with Special Reference to the Etiological Relationship of the Bacillus Coli. By Albert G. Nicholls, M. D., of Montreal. [Reprinted from the Montreal Medical Journal.]

Concerning Immunity and the Use of Normal Non-immunized Serums. By W. Thornton Parker, of Westboro, Massachusetts. [Reprinted from the International Medical Magazine.]

The Importance of Blood Examinations in Reference to General Anaesthetization and Operative Procedures. By Hamilton Fish, M. D., of Ouray, Colorado. [Reprinted from the Annals of Surgery.]

Hay Fever. By Carols M. Cobb, M. D., of Lynn, Massachusetts. [Reprinted from the Philadelphia Monthly Medical Journal.]

La neurasthénie et certaines affections du nez et de la gorge. Par Marcel Natier. [Extrait de La Parole.]

Der Werth des Naftalan in der Therapie. Von Dr. A. Klug in Freiheit-Johannishad. Separat-Abruck aus der Wiener medizinische Presse.]

New Inventions, etc.

A NEW FORCEPS FOR ELECTRO-HEMOSTASIS.

By J. SHEARNE WIGHT, JR., M. D., BROOKLYN.

This forceps is designed to clamp broad pedicles, thin them out, and desiccate them. They can be cut through without requiring a ligature to arrest the haemorrhage. The stump left is not carbonized and takes up a new blood supply, becoming organized. The clot forms for some distance in the vessel, and the latter will withstand a pressure of about sixty pounds to the square inch.

The length of the jaws is three inches, the width less than three eighths of an inch, the thickness about three sixteenths of an inch, the length of the handles is five inches and three quarters, and the jaws are covered
with vulcanized rubber, except on their inner surface, to protect the surrounding tissues from injury by heat.

Third, the alcohol protected the material of the body from consumption just as effectively as the corresponding amounts of sugar and starch. That is to say, whether the body was at rest or at work, it held its own just as well with the one as with the other.

Laparotomy for Perforated Typhoid Ulcer.—Professor Kennedy Dalziel, of Anderson’s College, Glasgow (Scottish Medical and Surgical Journal, July), concluding a paper on this subject, says that it must now be accepted that operative interference in perforation is not only justifiable but imperative, and that to secure a full measure of success it must be done early, and not, as was the case till a few years ago in intestinal obstruction, be put off till only a “last chance” is offered instead of what ought to have been the “first.”

The Petition of the Unborn.—Dr. J. W. Ballantyne (British Medical Journal, April 15th), in a paper on Antenatal Therapeutics, thus voices, in the form of a petition, what he conceives to be the claims of the unborn: “We, the unborn, do here humbly set forth our right to be well born. We do not demand that we shall be born of wealthy parents, for we know from the sad experience of others once unborn like ourselves that millions of money without an hour’s complete health to enjoy it is gall and bitterness. Neither do we ask that we shall be born of a titled stock; we prefer good blood to the much-vaunted blue blood with a notorious deficiency in white corpuses. We do not petition for parents with a hereditary history free from all blots and blemishes, for we know that such are not to be had; it will suffice us if we are provided with four long-lived grandparents, and with a father and mother who, in the words of one of the post-natal poets, have ‘self-reverence, self-knowledge, self-control; these three alone lead us to sovereign power.’ We ask to be protected from the fathers who in the very springtime of their lives, when they ought to have been sowing health and strength, were sowing disease and death, ‘wild oats’ they called them, with a miserable attempt at self-deception. We object to springing from body cells weakened by abuse and toxic and pathogenic agencies. We wish publicly to express our abhorrence for fathers like the one to whom our friend, M. Fournier, refers, who, after his wife had thrice aborted and once given birth to a hydrocephalic fetus, all of them the stigmata of his sypbilitic taint, came whining a tardy repentance:

“Ah, docteur, si j’avais su. Si j’avais réfléchi à ce qui m’arrive aujourd’hui, si l’on m’avait prévenu de cela, je ne me serais certes pas marié. La perspective de ce qui peut arriver à mon enfant et à sa mère est pour moi un tourment de tous les instants. Je n’en dors plus. Cette pensée empoisonne ma vie.”

“From such fathers we pray that we may be spared, for well we know that their whining repentance means little, and that when we grow up with the signs upon our bodies and in our minds of a parent’s fall, they will not look upon us with pity, but with loathing, even as we
also look upon them. Neither do we wish to have anything to do with the mother—we blush for her—who does herself and us with noxious oxytocic drugs at the second and third month of pregnancy in order that she may be saved from what she regards as the irritating interference and exasperating suffering of childbirth. Such conduct makes our pulses throb with righteous indignation from the foramen ovale to the very tips of our choric villi. We confess that we are absolutely unable to understand the attitude of a mother who will do such a thing "avec le cœur léger," and who will on another occasion shed floods of tears and become hysterical with grief over the dead body of a month-old baby, or, horrible dictum, of a favorite dog. Some of us hope to be mothers ourselves some day, and we trust we shall not so illogical, not so wicked, as to act in such a manner. We do not prefer to have as parents individuals who are tuberculous or predisposed to tuberculosis, who are congenitally deformed, or who belong to a stock in which cancer and insanity have been frequent incidents; but we do not absolutely refuse to admit their rights to maternity and motherhood so long as they are themselves clean-living and right-thinking folk, for we have a great belief in the tendency of the germ plasm to return to right physiological paths if it only gets a fair chance. We think that much of the evil that is done to the germ in one generation may be undone in the next, but of course with great difficulty, for factis descensus averni, sed revocare gradum hic labor hoc opus est. We do not particularly object to having first cousins as parents when they both have a clean bill of health, but we do not wish to be the public demonstration of the intensification of morbid processes which will result if they have not. Finally, we formulate our claim and state our right to be engendered by self-respecting individuals, to be conceived in soberness, and to be developed under healthy conditions of intra-uterine life.

A Banquet in Honor of Dr. Emily, of the Fashoda expedition, was given at the Grand Hotel, Paris, on June 8th. The Tribune médicale for June 21st contained a copy of the menu. Among the dishes were consommé Savorgnan de Brazza, suprêmes de sole Marchand, sel de daguet de Loango à la Baratier, mamelons de pedrœce Fashoda, salade congolaise, turbans d'axam na l'éthiopienne, bombe Emily, and friandises Djibouti.

The French Association for the Advancement of the Sciences will hold its annual meeting at Boulogne-sur-Mer from the 14th to the 21st of September. The new subsection of medical electricity will sit for the first time, under the presidency of Professor J. Bergonie, of Bordeaux. The programme includes the following items: The Electrolytic Treatment of Strictures, particularly those of the Urethra, by Dr. H. Bortier, of Lyon; Stereoscopic Radiography and Radiography, by Professor Marie, of Toulouse; Recent Progress in Radiography, by Professor Imbert and Dr. Bertin-Sans, of Montpellier; and Endodiagnosis, its Techniques and its Results, by Dr. Bouchacourt, of Paris. A statue of the late Dr. Duchenne, the famous medical electrician, will be inaugurated.

Absence of Self-restraining Power in a Man Convicted of Public Indecency.—M. Bérillon (Indépendance medicale, June 28th) recently presented to the French Society of Hypnotism and Psychology a patient who had been convicted of indecent behavior, and pointed out that he was the subject of urethral strictures, one situated in the bulbar and one in the membranous portion of the urethra; to the latter one spasm was superadded. These lesions, M. Bérillon considered, were the explanation of the reflex nervous troubles which resulted in the acts for which he was prosecuted. At certain times, under the influence of urethral irritation, the patient fell into a state of genital erethicism, inducing the automatic accomplishment of indecent acts. Under the influence of genital irritation the spinal centres were relieved from the controlling psychomotor influence of the cerebrum; the lower centres became independent, functioning irresistibly. The man was deprived of controlling power, whence he ought not, in the author's opinion, to be held responsible for irresistible reflex impulses. The treatment required to be directed both to remove the cause of the impulses and to increase the power of self-control.

Christian Science and Law.—The American Medical Quarterly for June says on this subject that a healthy moral tone supporting the existing statutes is far better than to attempt any alteration in the same, as there is already sufficient groundwork on which to suppress all attempts at quackery or charlatanism. The forcefulness of a statute depends largely upon its interpretation, and if the people are aroused to the dangers that come to them because of methods which obtain at the present time, existing statutes are all-sufficient to punish malefactors. The moment laws are put upon the statute books which define more clearly than do the existing ones a method for punishing Christian Scientists and other healers, that moment the charge of persecution will be lodged against the profession of medicine and against the district attorneys as prosecuting officers. These people flourish under persecution.

"By their deeds ye shall know them," and by the evil effects that follow the attempts at cure in cases such as have been recently cited in the newspapers, and which have attracted the attention of the public as well as of the State and local officials, unless steps are taken to prevent the prosecution under specific statutes. There is no decision confirmed by the highest courts in the land which defines "the practice of medicine," each State being left to determine this matter for itself; and that, for instance, has been the difficulty in the past and will be the difficulty in the future in regulating the practice of midwifery, unless midwives themselves are regularly licensed by the State to do this work, and others are prevented from practising this branch of physiologic medicine.

If procedures are commenced against men and women who honestly believe that they can be cured of bodily ills by faith, we shall antagonize an element which will be strengthened by reason of such prosecution. The public can be safely left to judge as to the merits of the methods of their attempted cures. If President Murphy, of the New York board of health, and others occupying similar positions, will, as cases are reported in the public prints, expose the fallacy of the methods which these misguided folk employ, it will do far more toward changing the opinions of people as to the merits of such procedure than could any law or hundreds of laws which might be enacted by legislatures.

It is a sociologic question more than a medical one, a question of morals rather than of law, and the American Medical Quarterly would oppose any procedure
which would bring about a legal prosecution based on the
theory that religious thought and action should be interfered with.

There are many truly good people who believe in
Christian Science (which has been described as a mis-
nomer because it is not Christian and because it is not science); they would feel themselves persecuted were
the law to attempt to curtail their rights in this man-
er. Those who would prosecute them would do so on
the theory that the greatest public good would be served by
lessening the field of their usefulness, but, as previously
stated, it would be looked upon by the disinterested and the uneducated, as well as by members of such
a sect or creed, as an interference with their religious
methods, and in the end would do more harm than good.

The present medical laws should not be amended ex-
cepting after careful review by doctors and lawyers,
and then simply on lines which will prevent a person
practising as a doctor of medicine without having re-
tained the sanction of the State, by virtue of having
passed the medical licensing examination prescribed in
the commonwealth wherein he or she resides.

Death of Sir William Henry Flower, F. R. S.—The
Lancet for July 8th gives an obituary notice of Sir
William Flower, formerly director of the Natural His-
tory Department of the British Museum, who died in
London on July 1st. Sir William’s scientific work was
laborious, and among his writings of special interest to
the medical profession may be named An Introduction
to the Osteology of the Mammalia and Diagrams of the
Nerves of the Human Body. Sir William Flower was
formerly an assistant surgeon in the British army, and
served with the Fifty-third Regiment (Shropshire
Light Infantry) through the Crimean War, receiving
the Crimean Medal with four clasps and the Turkish
Medal. He was a Fellow of the Royal College of Sur-
geons, and formerly conservator of the Hunterian Mu-
seum of that college.

"Kissing" and Other Bugs.—The New York Times
for July 19th reports the ease of a death certificate is-
sewed in Chicago in the following terms: "Chief and
determining cause of death—sting of a kissing bug;
consecutive and contributory tonsillitis." Needless to
say, the ease was referred to the coroner. The "strang-
ing bug" is the latest candidate for the post of jour-
nalistic honor that in former days used to be given at
certain seasons of the year to the "sea serpent." From
the same paper we learn that the strangling bug appears
in clouds, lightning on the throats of people, flying into
their faces and ears and almost "strangling" them. It
is said to be recognized by an African traveler as a well-
known denizen of the interior of that country.

The Acme of Sexual Ignorance.—The Quarterly
Medical Journal for July, quoting from the Review of
Reviews, says that Mr. J. G. Frazer contributes the first
part of an article on The Origin of Totemism to the
Fortnightly Review for April. It is based chiefly upon
the book by Mr. Spencer and Mr. Gillen on The Native
Tribes of Central Australia, which has just been pub-
lished by Messrs. Macmillan. Mr. Frazer says that the
book contains a full description of the most extraordin-
ary set of customs and beliefs ever put on record. The
natives, whose customs are described by Messrs. Spence-
cer and Gillen, are so devoid of what may be called
ordinary common sense that, although they suffer se-
verely from frost at night, they have never yet learned to
use the furs of the animals which they kill as cloth-
ing. They huddle naked round little fires, into which
they frequently roll when sleeping and burn themselves.
Even this, however, is a less extraordinary illustration
of their difference from the rest of mankind than is to
be found in their theory as to the propagation of the
species. Mr. Frazer says: "They have no notion that
mankind is propagated by the union of the sexes—indeed,
when the idea is suggested to them they steadfastly
reject it. Their own theory to account for the
continuation of the species is sufficiently remarkable.
They suppose that in certain far-off times, to which
they give the name of 'Alcheringa,' their ancestors
roamed about in bands, each band consisting of mem-
bers of the same totem group. Where they died their
spirits went into the ground, and formed, as it were,
spiritual storhouses, the external mark of which is
some natural feature, generally a stone or tree. Such
spots are scattered all over the country, and the ances-
tral spirits who haunt them are ever waiting for a fa-
avorable opportunity to be borne again into the world.
When one of them sees his chance he pounces out on a
passing girl or woman and enters into her. Then she
conceives, and in due time gives birth to a child, who is
firmly believed to be a reincarnation of the spirit that
 darted into the mother from the rock or tree. It mat-
ters not whether a woman be young or old, a matron
or a maid, all are alike liable to be thus impregnated
by the spirit—although it has been shrewdly observed
by the natives that the spirits on the whole exhibit a
preference for such women as are young and fat.
Accordingly, when a plump damsel, who shrinks from the
burden of maternity, is obliged to pass one of the spots
where the disembodied spirits are supposed to lurk, she
disguises herself as a withered old bag and hobbes
past, bent up double, leaning on a stick, wrinkling her
smooth young face, and mumbling in a cracked and
wheesy voice, 'Don't come to me, I am an old woman.'
Thus, in the opinion of these savages, every conception
is what we are wont to call an immaculate conception,
being brought about by the entrance into the mother of
a spirit apart from any contact with the other sex. Stu-
dents of folklore have long been familiar with notions
of this sort occurring in the stories of the birth of mi-
raeous personages; but this is the first case on record
of a tribe who believe in immaculate conception as the
sole cause of the birth of every human being who comes
into the world. A people so ignorant of the most ele-
mental of natural processes may well rank at the very
bottom of the savage scale."

The Teeth of the Young.—The British Medical
Journal for July 8th, in an editorial comment on the
Teeth of the Schoolboy, urging the necessity in England
of a periodical examination of children's teeth, says:
"While agreeing with the numerous dentists who have
written concerning the decay and care of the teeth, we
are of opinion that it is not alone after the eruption of
the teeth that care should be exercised. The future of
the teeth as well as the future of the body depends for
the most part on the care of the child during the early
years of its existence, and it is more important to con-
sider the subject of children's teeth during their develop-
ment in the gums and before they have erupted than
even to check decay when they appear or to scoop out
micro-organisms from their sockets. This aspect of the
hygiene of the teeth has yet to be dealt with."
A Doctor Princess and her Thesis.—According to the Écho médical du nord for July 2d, the Princess Guédroytz de Beléoroff has recently published in the Revue médicale de la Suisse Romande a remarkable paper as the result of work in Professor Roux's clinic at Lausanne, entitled Complete Evisceration of the Vesicula Seminalis and of the Vas Deferens in a Case of Castration for Primary Tuberculosis. The Écho comments on the singular subject of the medical princess's communication, appreciating at the same time the value of the communication, and says that the times move quickly, and it is probable that in a few years we shall see women specialists on the diseases of men, as we now find men specialists on the diseases of women. We should not be surprised if it were not some idea of carrying the attack into the enemy's country that actuated the royal lady doctor in her choice of a subject.

A Long Sleep.—The Journal de médecine de Paris and the Écho médical du nord, both of date July 2d, refer to the "Sleeper of Theneules." It appears that a young woman, Marguerite Boyenval, fell asleep abruptly as the result of strong emotion on May 29, 1853, and has slept continuously since that date without showing consciousness even for a quarter of an hour. She is now thirty-five years of age, which period sixteen years, or nearly half, have been spent in a cataleptic condition. She is said to be almost a skeleton, which is small wonder, seeing that she has been kept alive with difficulty by nutritive enemata only. Her pallor is described as ghastly, yet her pulse beats over eighty to the minute. She lies with her hands joined; but if the arm is raised, it remains so until forcibly lowered. The entire surface of her body appears to be devoid of sensation. If the story is true, this sleep is undoubtedly a record breaker.

A Memorial Bust of the Late Professor Rutherford, F. R. S., was unveiled by Sir William Muir, principal of Edinburgh University, in the physiology class room of that institution on July 8th.

Cerebro-spinal Meningitis without Fever or Retraction of the Neck.—Mr. David A. Belilios, M. R. C. S. (Lancet, July 15th), referring to a case mentioned by Dr. Osler in the Lancet for June 21st in which these two classical symptoms were absent, records a similar case in which fever and retraction of the neck, usually supposed to be almost pathognomonic of the disease, were absent, the case, however, presenting other signs distinctive of cerebro-spinal meningitis.

Mr. Havelock Ellis's Work on Sexual Perversion.—In an editorial annotation the Lancet for July 15th cites, if not approvingly, at least without adverse criticism, the trenchant remarks on this subject of Dr. William Lee Howard, of Baltimore, as follows: "In two of the June numbers of the Maryland Medical Journal Dr. William Lee Howard, of Baltimore, blames the unwillingness of some medical men to treat patients whose symptoms, whether bodily or mental, are related to the sexual organs or functions, and he vigorously denounces the prosecution last year of the London agent for the sale of Mr. Havelock Ellis's book, Sexual Inversion. He maintains that a recognition of the pathological states of the sexual centres as demonstrated in certain psychical conditions and morbid acts, together with a full comprehension of the power of association and suggestion in the adolescent sexual neuropath, are essential for medical practitioners, and he argues that if a pathological state such as congenital sex perversion is too disgusting to be recognized, then a pathological state producing syphilitic sores of the genitals ought by parity of reasoning to be too filthy to be treated. He had been hoping that Mr. Havelock Ellis's prohibited book would have had the effect of bringing English medical men and publicists to understand that a human being is just as liable to have the growth in the cells making up the sexual centre disturbed and distorted as in the cells making up any other centre, physiological or psychical, from which it follows that it is unreasonable to send a man to prison because he is deformed in certain psychical centres. Mr. Ellis's book he describes as a classic, saying that it is cleaner, has more of the scientific atmosphere, and shows greater study and research than any of the works hitherto published on the subject, not excepting those of Krafft-Ebing or Schrenck Notzing.

Chicago Humor.—According to the Chicago Medical Recorder for July, Dr. Hibbert W. Hill, bacteriologist to the Boston board of health, has examined cultures taken from the transmitters on some of the most frequently used public telephones in Boston, and has found no pathogenic bacteria, merely the "hay bacillus" and one or two other harmless varieties. It is, says the Recorder, now in order for New York papers to express their surprise at the absence of the "bean bacillus."

The Right to Revoke a License to Practise.—According to the Chicago Medical Recorder for July, the supreme court of Iowa recently rendered a decision declaring that the State board of medical examiners possessed the right to revoke the license of any physician whom it considered incompetent to practise medicine.

The Validity of an Habitual Drunkard's Will.—According to the Evening Sun for July 22d, Surrogate Varmus on that day dismissed a contest on the admission to probate of a will, opposition to which was based on the ground that the testatrix was an habitual drunkard. The will was contested by a daughter to whom but a small sum was left, the bulk of the property being left to "strangers in blood."

The surrogate said: "The worst drunkards have times when they are sober, and have perfectly lucid intervals when their acts are legal and valid. The fact of habitual drunkenness raises no presumption that at the time the act was done the inebriate was intoxicated."

Upon the general subject of intoxication the surrogate also remarked: "A dissipated person is not precluded from making a contract or executing a will, even though he be partly under the influence of liquor when performing such acts. If fixed mental disease has resulted from such indulgence, or the person is so excited thereby as not to be master of himself, then only are his legal acts void. Less mental capacity is required to execute a will than a contract or a deed."

A Doctor's Carrier Pigeons.—Going abroad for news at home, we learn from the Journal de médecine de Paris for July 2d of a doctor in the State of Nebraska who, practising in a sparsely populated district with long distances to travel, makes use of his carrier pigeons to bring him bulletins of progress from patients, whereby he is enabled to dispose his visiting list to the best advantage.
Original Communications.

THE AMERICAN SOLDIER AND VENERAL DISEASES.
A REFUTATION OF SOME OF THE STATEMENTS OF MR. EDWARD ATKINSON.
BY WILLIAM A. HAMMOND, M.D.,
BRIGADIER-GENERAL AND SURGEON-GENERAL, U. S. ARMY (RETIRED).

Perhaps of all the classes of men throughout the world soldiers are more frequently the subjects of venereal diseases than any other. This proclivity is due not altogether to circumstances incidental to army life, but to a great extent to the fact that military men of all ranks, from the field-marshall to the private, have in every age of the world evidenced a marked tendency to become the victims of female blandishments, and have, moreover, been the special favorites of the fair sex both of high and low life. A long experience not only as a medical officer of the army, but as a practising surgeon among civilians in and out of hospitals, and very thorough observation of civil and military hospitals, both in this country and in Europe, have given me extensive opportunities for studying the class of diseases in question in their relations to the American soldier, and have prompted me to extend my researches into the subject as regards the armies of other nations. I am, therefore, I trust, not altogether deficient in the knowledge necessary to place a very important subject in its true position before the medical profession and the public generally.

The erroneous statements in Mr. Atkinson's pamphlet, The Hell of War,* if allowed to go uncorrected, are calculated to do very great harm, coming, as they do, from a gentleman whose conclusions have hitherto been so uniformly based on facts, and whose position as a political economist adds greatly to the force of his remarks. But on the present occasion he has ventured into waters beyond his depth, and, not only this, but into waters of different quality from those in which he has hitherto waded. I shall not quote the proverb Ne sutor supra crepidam as being entirely applicable to him, for his mind is so thoroughly trained to habits of research that it does not require much labor for him to obtain a moderately correct idea of any subject, no matter how foreign it may be to the general trend of his studies. But, in the present instance, a "moderately correct" idea will not answer. Absolute truth is required. A more thorough investigation than he has given the subject would, I am confident, have convinced him of his errors; and then, as honesty is his distinguishing characteristic, he would not have fallen into the mistakes which the science of the present day is so readily capable of demonstrating.

* The Hell of War, p. 17.

In the first place, and in striking exemplification of the fact that Mr. Atkinson does not know what he is talking about, is his confounding of venereal diseases with syphilis, evidently under the impression that the two are correlative terms. From this confusion he draws the inference that they are all capable of contaminating the blood of the person affected and of transmitting infection to progeny from generation to generation. Thus he says: "The greater cost will be the corruption of the blood through the infection of every force that will be annually called out to maintain our rule." And again—

"The greatest and most unavoidable danger to which these forces will be exposed will be neither fever nor malaria; it will be venereal diseases in their worst and most malignant form." And again—

"It is well known that while there may be an apparent cure, this disease [venereal disease] works corruption of the blood to the third and fourth generation, ending in degeneracy."

Now, under the designation of "venereal disease," as the term is used by Mr. Atkinson, and in the tables of statistics from which he quotes, are included:
1. Soft chancre or chancreoid, as it is generally called.
2. Gonorrhoea.
3. The true syphilitic or infecting sore—the hard chancre.

This is the only one that possesses the slightest claim to the quality of infecting the general system and thus producing constitutional syphilis. The other two are simply local diseases which are treated locally, and the poison of which is, under no circumstances, absorbed into the blood so as to produce constitutional disease capable of being transmitted to the offspring.

In the early part of my professional service in the army I was stationed in New Mexico, which at the time had an unenviable reputation as a hotbed of syphilis. There was then (1849-52) no distinction between the hard and the soft chancre, both being considered by the medical profession generally as competent to cause contamination of the blood and thus produce constitutional syphilis. The view held was similar to that which Mr. Atkinson holds now; but since that period fifty years have elapsed, and with the progress of medical science the fact has been established beyond question that only one of the so-called venereal diseases—the hard chancre—is capable of affecting the general system. I soon observed that only a few cases of venereal ulcerations were followed by general symptoms; but it was reserved for Ricord, the eminent French syphilographer, to point out the essential difference between the two primary sores and to establish beyond the shadow of a doubt that the soft chancre, or chancreoid, is never a source of constitutional syphilis. Mr. Atkinson ignores this distinction, and as the soft

Chancre is much more commonly encountered, especially in hot climates, than the infecting or syphilitic sore, the force of his statement relative to the dangers to untold generations of Americans from the return of our soldiers, is, by this circumstance alone, materially lessened. The soft chancre is amenable to treatment by local measures, and if any soldiers should succeed in reaching the United States with unhealed chancreoids, or non-infecting sores, the only persons liable to suffer would be the women with whom they might have illicit relations, and they would only be involved in like manner with themselves. The Philippine Islands are especially noted for the readiness with which venereal diseases of all kinds are cured, and this without any treatment whatever except such as the climate affords. It is not likely, therefore, that any but a very small proportion of soldiers suffering from such affections would arrive in the United States with the ability to communicate even a non-infecting chancreoid. Thus, Sir John Browning, while stating that venereal diseases in the Philippines are widespread, declares that they are easily cured by the simple remedies used by the natives. The ready subjection of these affections, as they exist in the Philippines, to medical treatment, is the uniform testimony of all familiar with the subject whom I have questioned. And the assertion of Mr. Atkinson, that they prevail there in their "worst and most malignant form," is not borne out by the facts. They are more virulent in the slums of our large cities than they are in any of our recently acquired tropical possessions. The moist climate of the Philippines, accompanied as it is by high temperature, is calculated to eliminate the syphilitic poison from the system in a manner similar to that exercised by the Hot Springs of Arkansas. If they were near to this country it would be good medical practice for physicians to send their syphilitic patients to them in order to produce quicker and more effectual cures.

The other affection coming under the head of venereal diseases—gonorrhea—is likewise incapable of producing constitutional disease, except in the rare instances in which it appears to predispose to rheumatic affections of the joints. But no one contends, except perhaps Mr. Atkinson, that this condition can be transmitted either to the mother or the offspring. In fact, gonorrhea is only communicable by actual contact with the specific gonorrheal bacillus, and in this respect is analogous to chancre.

Nothing is left, therefore, of Mr. Atkinson's venereal diseases and their transmission to numerous unborn generations but the hard, the infecting, the true syphilitic chancre; and this constitutes but about one seventh of all venereal diseases. Thus, taking the data furnished by the surgeon-general in his report for 1898, we find that for the year 1897 the ratio for the venereal diseases was 84.59 to the 1,000 of mean strength in a total of 27,374, while of this ratio only 12.94 to the 1,000 were syphilis.

Syphilis has long labored under the imputation of being transmissible from the infected father to the offspring. But it is now scarcely a question for doubt that such an event never takes place, and that the only ways for the unborn child to acquire syphilis are by passing over—while in process of entering the world—primary sores, and by the mother contracting such sores during the first six months of her pregnancy; and even this latter is a contingency not likely to happen. Now, as it takes at least six weeks for a transport to reach any port in the United States, and as the duration of most chancre, even without medical treatment, rarely exceeds a month, many of the soldiers suffering from such sores would be free from them, and therefore incapable of communicating the disease, even though they might be affected constitutionally. Only those whose primary lesions were still unhealed could transmit syphilis to offspring by giving primary sores to the mother, and thus, possibly, causing in her constitutional disease. For it by no means follows that a person with a true syphilitic chancr can transmit the poison to the person with whom he or she has intercourse. Syphilis is like small-pox and other contagious diseases. Many may be exposed to infection and yet never become infected. Then, admitting that a woman contracts syphilis from an impure connection with a soldier recently returned from the Philippines, in order that she may transmit the disease to her offspring, she must acquire constitutional syphilis during the first six months of her pregnancy, and even then the chances that the child will be infected are remote. Moreover, it must be borne in mind that it is by no means certain that the mother having a primary sore from an infected soldier would acquire constitutional syphilis. Many persons, male and female, escape infection of the system, even though having local specific lesions, just as many persons, though exposed to contagion, escape scarlet fever, diphtheria, measles, small-pox, etc. It is probable that only a small proportion of those who render themselves liable, even though taking no precautions in avoidance, acquire syphilis.

A main point to be insisted upon is that constitutional syphilis is never transmitted by the father either to the mother or child, but that except as mentioned in regard to the infection of the offspring by the mother, actual contact with a primary lesion is necessary.

That this is the view held by the best authorities, and taught in the text-books and in our medical schools, is shown in the following citations:

Sturgis, in his paper on Hereditary Syphilis, collects much evidence to show that syphilis in the unborn child occurs only when the mother is the subject of the disease; the existence of the affection in the father

* A Visit to the Philippine Islands, London, 1859, p. 83.

being a matter of no importance so long as the mother does not become infected by him from a primary lesion.

Van Buren and Keyes say: “Fathers with tertiary syphilis, certainly, as a rule, when the mother is sound, procreate healthy children as far as syphilis is concerned.”

Otis† says: “In order, therefore, to the production of the disease in the adult, in the infant, or in the embryo, the infecting cell of syphilis must first be brought into contact with healthy cell material. No mysterious hereditary influence is necessary or can be admitted.”

And again: “But that any syphilitic disease proved to be such by its power to transmit syphilis has been communicated to healthy persons by infants conceived after the active or contagious stage of syphilis has passed, there is no well-authenticated evidence to prove.”

And again: “Cases of syphilis] reported during such infection to have occurred through the sole agency of the father suffering from syphilis (the mother up to this time being free from the disease) must be classed either among those instances where the characteristic features of the disease are absent, or where they are so imperfectly developed as to have escaped detection.”

Dr. Shaw-Mackenzie,* in his monograph on Maternal Syphilis, speaking of Mr. Henry Lee’s statement to the effect that in so-called hereditary syphilis due to the father, there has been a urethral or concealed chancre, says:

“It throws a reasonable doubt on the spermatozoan as an accepted vehicle for virus in the absence of diseased testes, and authoritatively admits the maternal origin of syphilis in the vast majority of cases.” He afterward reiterates this opinion, and declares that it is sustained by all the facts that can be adduced.

Dr. Ogilvie, in his instructive paper on Congenital Immunity to Syphilis,* says: “Without denying the possibility of a paternal influence of this kind [the infection of the unborn offspring through the father], or a maternal one during the mother’s tertiary stage, or after her recovery, I have only indicated the direction in which all the actual evidence which we possess on this subject seems to point.” This evidence, he declares throughout his monograph, is overwhelmingly to the effect that constitutional syphilis existing in the father is not transmitted to the offspring under any circumstances whatever.

There is no possible way for a man suffering from constitutional syphilis to infect a healthy woman but through the seminal fluid which has become contami-

* A Practical Treatise on Genito-urinary Diseases, with Syphilis, New York, 1874, p. 521.
† Practical Clinical Lessons on Syphilis, etc., New York, 1883, p. 205 et seq.

nated through the absorption of the syphilitic virus into his blood. But, as a matter of fact, it never is thus poisoned. No one has yet succeeded in producing a chancre or other syphilitic manifestations by inoculating animals or healthy persons with the seminal fluid of a syphilitic man. Fournier* says: “Being given a syphilitic father and a healthy mother, there is every chance that the child born of the union will be exempt from syphilis.” And again, “I have under notice eighty-seven cases of syphilitic men who, having married, have not communicated to their wives the least suspicious symptom, and from whose marriage one hundred and fifty-six perfectly healthy children were born.”

The researches of Mireur† are perfectly conclusive on this point of the non-inocuability of the seminal fluid of syphilicides confirming, as they do, the experiments of Fournier. And it may be regarded now as being definitely established that such inocuability does not exist. As Hochsinger‡ says: “It is thoroughly well known, and, through the experiments of Fournier and Mireur, established beyond doubt that the semen of a syphilitic man as such can not communicate syphilis.”

At the present day, he repeats, it is regarded as impossible that the semen of a syphilitic man can transmit the infection to a healthy woman.

In fact, syphilis can not be communicated to healthy persons through the physiological secretions or excretions of syphilitic men or women. Thus, neither the tears, the sweat, the urine, the milk, nor the semen contain the syphilitic virus. And, therefore, no matter how they reach the system they can not transmit the disease. A healthy child, for instance, may with impunity take into its stomach the milk of a syphilitic woman, or such milk may come in contact with abrasions in its mouth, and it will remain uninfected.

Up to about twenty-five years ago some authors, following Paraeelsus, Swedlaier, Astruc, and Ulrich, von Huten, contended for the hereditary transmission of syphilis through the father. But at the present day the best authorities—those basing their opinions on observation and experiment—absolutely deny such paternal influence. If there are any writers who still hold to the doctrine in question they are such as have obtained their information from antiquated treatises which have long since been put aside. There are some who still believe in the therapeutical virtues of sarsaparilla, or in the identity of the hard and soft chances, or in any one or more of a dozen exploded notions. There are others who refuse to accept the fact that mercury is curative of syphilis in some of its manifestations, and again others who deny the efficacy of quinine in malarial fever. There will always be such persons, not only in the medical profession but in all
the other walks of life—persons who are not convinced by facts, but who are governed by heated emotions instead by the cold intellect, which alone serves man in his search for truth.

So much for the hereditary transmission of syphilis, on which Mr. Atkinson, with a view of terrifying the people and discouraging the soldiers serving in our foreign possessions, has so vehemently insisted in his pamphlet. And what becomes of his fallacious assertion so dogmatically expressed "that it is well known that while there may be an apparent cure, this disease works corruption of the blood to the third and fourth generation, ending in degeneracy?" And how unjustifiable his appeal to fathers and mothers, "How many of your own sons will you expose to sure infection and degeneration in the conduct of your philanthropic purpose?" Sure infection and degeneration! If there ever was a dictum utterly unwarranted by the facts, this is one.

Mr. Atkinson says (page 18):

"The records of the medical department and the testimony of visitors to our camps in this country, coupled with the observations of members of Congress with whom I have consulted, prove that this phase of the hell of war had taken firm hold of our troops before they had been exposed to the greater hazard at their points of destination in Cuba, Porto Rico, and Manila."

There is a very considerable substratum of truth in this citation. Undoubtedly a great deal of the gonorrhea, chancreoid, and syphilis which was found among our troops in the places mentioned by Mr. Atkinson was taken there from New York, San Francisco, and other parts from which troops embarked, and from which sources of infection the diseases in question were still more extensively than heretofore spread among the inhabitants of those islands. San Francisco was pre-eminent as a nursery of these diseases. Even during peace, some of the garrisons in the United States exhibited so large a proportion of venereal affections that they were worthy to come into competition with the numbers among the British troops in India, which are so triumphantly adduced by Mr. Atkinson without the slightest warrant as being applicable to our own troops in our tropical possessions. Thus it is stated in the Report of the Surgeon-General for 1894 that Columbus Barracks, Ohio, had the highest admission rate—333.88 to the 1,000 of mean strength. Fort Brown, Texas, comes next, with a ratio of 265.05, and even here at Washington Barracks the ratio was 167.47. As General Sternberg very appositely remarks: "The statistics sometimes fail to include the whole of the cases." And, again, in speaking of the prevalence of venereal diseases at Columbus Barracks, "the depot surgeon states his opinion that it is no uncommon occurrence for men so diseased to treat themselves, or get treatment outside without having their names appear on the sick report; and the post-surgeon at Fort Brady is confident that not more than twenty-five per cent. of the venereal cases at his post came under his observation."

In 1897 the absolute number of cases of all venereal diseases, as shown by the Report of the Surgeon-General for that year, was 1,361, of which only 276 were syphilis, preserving therefore the ratio of one seventh. The ratios were of all venereal diseases, for Jefferson Barracks, Missouri, 211.59; Fort Ringgold, Texas, 206.35; and Fort Leavenworth, Kansas, 184.70; at Columbus Barracks, it being no longer a recruiting depot, the ratio had fallen to 160.26; while at Washington Barracks it was only 136.75.

In 1898, during part of which the war existed, Jefferson Barracks shows a decrease to a ratio of 164.77; Fort Ringgold, Texas, has fallen to 186.99; and Fort Leavenworth, Kansas, to 134.04. Columbus Barracks shows a still further reduction to 147. As to Washington Barracks, it no longer figures among the twenty posts showing the greatest ratios, and as the smallest ratio is at Fort McPherson, Georgia—117.90—the ratio at Washington Barracks could not have exceeded those figures.

It is doubtful if syphilis existed in the Philippines, or in Cuba or in Puerto Rico before it was carried there by Europeans. It is certainly true that it was unknown in Hawaii before it was imported by Europeans and Americans. It seems scarcely fair then, in Mr. Atkinson, to turn around now on the people of those islands and taunt them with the crime of infecting our soldiers. If the population of Hawaii has, as he says, been reduced to a "degenerated remnant," it is because the diseases they contracted from the whites were not subjected to proper medical treatment. When scientifically managed no disease is more susceptible to cure than syphilis, whether primary or constitutional. As to leprosy in the Hawaiian Islands, which he declares "gives evidence of the utter degeneracy of these poor people," I should like to ask him how many Americans have contracted the disease there? Can he name a single one? And how about leprosy with the Norwegians among whom it prevails extensively. Is it an evidence of the degeneracy of these people? And does Mr. Atkinson know that this disease was not indigenous in Hawaii, but was taken there by the Chinese?

Mr. Atkinson omits all mention of the excessive use of alcohol as a factor in causing the degeneracy of the Hawaiian people, and, indeed, of all aborigines with which whites, especially Anglo-Saxons, are brought into contact. Neither does he allude to tuberculosis and small-pox; nor does he mention the fact, well known to anthropologists, that half-breeds are never so resistant to morbid influences as either of the parent stocks.

The statistics quoted by Mr. Atkinson from British sources relative to the prevalence of venereal diseases among the British troops in India and other British tropical possessions, and the use he makes of them, are calculated, if unexplained, to lead to erroneous conclu-
sions, and perhaps, as he evidently intends, to terrify the people of this country and the soldiers serving in our armies in foreign parts.

Relative to the increase in the spread of venereal diseases during the last few years, the success of the efforts of the ultra-good people of England in securing the repeal of the Contagious Diseases Act, must be charged with a great part of the odium therefor. While this act was in force the soldiers of the British army were inspected once a week by their medical officers, and therefore the first evidences of venereal diseases were discovered early. Moreover, the knowledge that they had to submit to such an examination had great influence in preventing the men exposing themselves to infection. General Coppinger, United States army, informs me that he observed at Plymouth the operation of the law. Among the soldiers who were inspected weekly there was very little syphilis or other venereal disease, while among the sailors who were not inspected there was a great deal.

Dr. Ogilvie declares that the amount of syphilis among the British troops serving in India has enormously increased, and that the disease has assumed a most virulent and malignant form. This, as he says, was first caused by the abolition of the Contagious Diseases Act, by the provisions of which the men had to be inspected every week.

The Report from Netley Hospital by the Committee of the College of Physicians states "that almost every variety of syphilitic disease was represented; those of a virulent form being very numerous, and the results of the disease were, in many cases, deplorable, while the appearance of the sufferers was most pitiable. Recovery is hopeless, and what to do with them has become a question of serious difficulty. It is impossible to send them to their homes; their friends refuse to receive them. Death alone can solve the difficulty."

I may here interpolate a question to Mr. Atkinson. A great many soldiers have returned from the Philippines, Cuba, and Puerto Rico. Does he know of the existence among these troops of any condition approaching, even remotely, this horrible picture of the state of affairs at Netley? I will answer for him. He does not. For there has not been the least resemblance to it; nor will there be.

Dr. Ogilvie remarks as follows on this scandalous matter:

"This is a most extraordinary picture of a disease which is generally considered one of the most controllable and best curative. The calamity during the Peninsula war, when the ravages were as notable as those in India at the present day was, as we have seen, chiefly due to the treatment adopted. The question therefore put in a leading medical journal: 'Is syphilis efficiently treated in the army?' seems eminently justifiable." Then he states that a committee appointed to inquire into a similar subject in 1868 found that no uniform plan of treatment existed in the forces at that time; and then continuing, says: "To obtain any answer to the above question an exhaustive inquiry into the details of the whole treatment and the hygienic conditions is necessary."

The above question is answered in the negative by the British Medical Journal, in which it appeared, and it quotes as follows from the Report of the Army Medical Department for 1891 showing how matters stood at that time:

"Formerly, and indeed at the present time, when a soldier contracts syphilis he is admitted to hospital and there treated until all the primary signs or symptoms of the disease have disappeared. He is discharged for duty, when all treatment is, of course, suspended; the disease breaks out afresh; he remains on duty as long as he can; he eventually comes to hospital, is readmitted, and under treatment the symptoms again disappear; he is again discharged for duty and treatment stops, and again the disease breaks out and again he is admitted to the hospital; and this series of events goes on. As he never gets a lengthened treatment, he never gets rid of the disease. He goes abroad to the tropics and is there an easy prey to the diseases common in those regions or the ravages of syphilis. Eventually he is either invalided, and is no further use as a soldier, or he dies."

"Was ever," continues the editor, "a more serious confession made in an official report? Is it any cause for wonder that the usefulness for active service and invaliding on account of syphilis is so great? May not the increased violence in the army reasonably be attributed to inadequate treatment?"

The prevalence of venereal diseases, especially of syphilis, among the British troops serving in India is, therefore, clearly the result of inefficient medical treatment, and is not due to the influence of climate or any specific virulence in the disease. This is conclusively shown by the improvement that has recently taken place. In an interesting paper on The Treatment of Syphilis in the Army by Intramuscular Injections of Mercury, Surgeon-Major Lambkin has proposed a plan of treatment from the use of which the reports already received are uniform in declaring that great amelioration has been effected. It consists in injecting into the muscles—preferably those of the gluteal region—a mixture of metallic mercury, one drachm; lanolin, two drachms; and carbolized olive oil, (two per cent.), one drachm. These ingredients are rubbed up together till the globules of mercury have entirely disappeared. The maximum dose of this compound is ten minims, and it is injected once, or at most twice a week. The advantages claimed for this method over the administration of mercury by any other process are:

* British Medical Journal, 1898, p. 487.
1. The soldier can be treated while out of hospital attending to his duties.

2. It is absolutely in the surgeon’s own hands, and therefore certain to be administered.

3. It does not produce diarrhea or indigestion.

The soldier is directed to attend the hospital at morning sick-call, and the injection being given, he rejoins his company without any interruption to his military duties having occurred.

The results given by Surgeon-Major Lambkin from several hundred cases coming under his own observation are exceedingly gratifying. Moreover, the experience of other medical officers is to the like effect. Thus, the surgeon-general of her Majesty's forces in India reports this plan as not only being generally successful in the treatment of syphilis, but as having also lessened the number of admissions into hospital for this disease.

Surgeon-Captain Porter reports most "happy results" from treatment by this system.

The director-general of the British army, in his annual report to the secretary of state for war, says: "Hypodermic injections of lanolin and mercury were found to give excellent results."

Another point upon which Mr. Atkinson insists, and which he thinks exhibits an exceptional state of filth and liability to infection in the cities of the Philippine Islands, is as follows:

"The precautions reported to me by commercial men who are thoroughly familiar with the conditions of these places, especially Manila, made necessary even on the part of private persons lest the infection should be carried from lavatories and the like, indicate the utterly corrupt condition of all the principal cities in these islands." This would be laughable if it were not calculated to deceive ignorant or thoughtless persons. It refers to a condition which exists with more or less thoroughness in every city of the civilized world, and in which the cities of the Philippine Islands possess, for instance, no exclusive or even marked preeminence. Who would, without precautions, expose himself to infection from such a source in London, Paris, or New York, or even in Boston? In fact, however, the danger of contracting venereal diseases from water-closets and the like is greatly exaggerated. In an extensive practice of over fifty years I have never observed such a case even among those who were not particularly cleanly in their habits. That the possibility exists is not to be denied. I know of no recorded cases, however, of syphilis having been thus acquired. Gonorrhea is occasionally communicated in this way, and Otis mentions two cases occurring in persons who had used the closets of hotels in this country, which were apparently caused by infection from these sources. But such events are rare, and even their possibility is doubted by some authorities. I have diligently questioned army officers who have served in the Philippines, and they know of no cases of infection from such sources. They state that the liability is no greater there than it is in any of our cities from similar agencies.

Now, as regards our own troops in the Philippines we have, as yet, no extensive or exact data in their relations to venereal diseases; but what little we have does not support Mr. Atkinson’s inference that because these affections are widespread among the British troops in India they must necessarily be equally prevalent among the American soldiers in the Philippines. I am informed by the surgeon-general that few medical reports have, as yet, been received, and that those that have come to hand make no reference to venereal disease as being especially prevalent or virulent. It is, however, stated by the chief surgeon of the Second Brigade, Second Division, Eighth Army Corps, stationed at Manila, that of 338 cases of disability, 89 were of venereal diseases. Of this number it should be borne in mind that only 13, or one seventh, were probably syphilis. This ratio is not so great as that of several army posts in this country. Mr. Atkinson might as well say that as Columbus Barracks shows a ratio of 333.38 to the 1,000 of mean strength, a similar proportion must exist at Newport Barracks, Kentucky, across the river from Cincinnati, Ohio. There is nothing on record showing any extreme virulence or refractoriness to treatment. All the information that I have been able to obtain orally from officers and others returning from the Philippines, shows that our troops are not suffering to a greater extent than the troops stationed in this country. It is a fact that the American soldier takes better care of himself than does the British soldier. He is more careful in not exposing himself to infection and much more cleanly in his habits. Moreover, it is his custom to report to his surgeon, or to some other medical authority, as soon as the first sign of disease is perceived.

Mr. Atkinson states that: "In the Philippines none of these precautions [sanitary] have been taken. No well-prepared stations exist, sanitary science is unknown, and our troops must be mostly volunteers under the direction mainly of inexperienced and ill-prepared line officers."

This is incorrect in every particular. There are excellent and thoroughly well-provided hospitals; sanitary requirements are in force and sanitary science is not unknown. Relative to the line officers, I can not make a sweeping assertion in regard to their fitness, but I have reason to believe that most of them know their duties and attend to them. As to the medical officers, all the evidence obtainable goes to show that they are well-informed and assiduous in the performance of their duties. We know that Manila and other places occupied by the American troops have been thoroughly
cleansed and disinfected. There are no special foci of disease there, and it is not likely that our troops will suffer more severely in any respect than if they were in camp on the shores of the Gulf of Mexico. Certainly they will not die or be disabled in anything like the proportion which existed among the troops composing the Army of the Potomac when they were serving on the Chickahominy.

The arguments used by Mr. Atkinson throughout his pamphlet are such as would, if acted upon, shut out Cuba, Puerto Rico, and the Philippine Islands from all communication with the rest of the civilized world. If his assertions are correct, he has proved too much. Commerce with them would be out of the question, for his statements are just as applicable to persons engaged in trading operations as to those serving in our army. No one, practically, contracts a venereal disease without his or her active cooperation. Soldiers are particularly apt to expose themselves to contagion; but lapses in this respect are by no means confined to them, and civilians living in foreign parts are notoriously less careful in the matter than such persons would be if residing in their own country. How much more worthy of Mr. Atkinson it would have been, if he had written, with his usual force and lucidity, a paper pointing out the evils of promiscuous sexual intercourse! This would have been a graceful act, for which his ability and researches in social science would have rendered him particularly capable. As it is, he has made statements which are not facts, has drawn inferences which are not warranted, and has expressed opinions which are unfounded. His hysterical and unpatriotic appeals to the people of the United States to discourage the recruitment of our army are unworthy of him. How far they will prevail with people influenced by his personal character, but ignorant of the facts, I do not know. But I do know that they will fall unheeded on the ears of the patriotic men who are fighting under the flag of their country.

ANÆSTHESIA:
NITROUS OXIDE; ETHER; CHLOROFORM.*

By S. ORMOND GOLDAN, M.D.

(Concluded from page 153.)

Nitrous oxide is a colorless gas of a peculiar sweetish, pleasant taste and slight odor. It is produced by the decomposition of ammonium nitrate; four gallons weigh one ounce. It is liquefied with a pressure of thirty atmospheres, with moderately intense cold, and is stored in steel or iron cylinders which are made to withstand a pressure many times that of the contained gas. The cylinders are made of capacities varying from twenty-five to a thousand gallons, the twenty-five, fifty, and one-hundred-gallon bottles being quite portable. The English cylinders with pedal attachment for regulating the flow of gas are far more convenient than the American pattern. When the gas is used at the patient's residence, two cylinders should always be taken. This precaution always insures a sufficient supply of gas, as there is no ready means of determining when a cylinder is nearly exhausted.

![An English gas cylinder with pedal attachment adjusted.](image)

Those who wish to become anaesthetists should first learn to administer laughing gas. While it is the safest anaesthetic, it requires the undivided attention of the administrator. He so acquires the habit of giving his entire attention to the process that he will not fail to do so when using the less safe anaesthetics, rather than observing the steps in the operation, which he so frequently does. Nitrous oxide is comparatively little used in this country except for the extraction of teeth, as the usual objections to its more general use in surgery are that it requires great skill for prolonged anaesthesias, and the apparatus is not easily portable and is expensive. It certainly is heavier than an ether or chloroform apparatus, but I have never experienced any inconvenience from the weight of it. If hospital interns were properly instructed in the administration of the gas many operations could be performed with its use where now ether and chloroform are necessary.

The advantages of nitrous oxide are its safety, rapidity, and absence of after-effects; its disadvantages are the skill required, and the fact that it does not relax the muscles as ether and chloroform do. It is indicated—

In any operations in which complete and prolonged muscular relaxation is not necessary; it may be said that on account of the venous oozing it is unsatisfactory in operations of delicate dissection. As a preliminary to ether in general anaesthesia it is unexcelled, and, unless contraindicated, there is no better method of inducing narcosis.

To replace chloroform as a preliminary to ether.
To replace chloroform for surgical and gynaecological diagnostic purposes.
When ether and chloroform can not be employed.
For removal of sutures.
For opening and curetting of abscesses. For excision of ingrowing toe nails. For circumcision, internal urethrotomy, and mebutotomy. For removal of tonsils and adenoids. For reduction of dislocations and setting fractures. For posterior colpotomy. For uterine curettage, etc.

It is contraindicated in the cases of very large and obese patients; in any condition causing stress upon the right heart, in which increase in arterial tension is unsafe; in arteritis, atheroma, aneurysm, alcoholism, and drug habits, such as opium, cocaine, etc. It should be remembered, when using the gas before ether, that even in very stout patients, who do not take nitrous oxide well, the gas may be given, if continued only to the point of unconsciousness, and then replaced with ether—that is, it is not always necessary to fully anesthetize the patient with nitrous oxide before changing to ether.

The apparatus for the inhalation of nitrous oxide alone consists of an inhaler with an inspiratory and expiratory valve and a stopcock, which automatically stops the flow of gas. Connecting the inhaler with the gas bag, there are from four to six feet of wide-calibred, silk-covered rubber tubing, which is wired throughout its entire interior. There are also a gas bag of from four to seven gallons capacity, a yoke to attach to the gas cylinder, and a key for turning on the gas.

In order to administer nitrous oxide successfully certain principles must be observed:

The gas must be pure; this is best assured by using it from the iron or steel cylinders in which it is compressed. In one instance the gas, after having been used and set aside for a period of eighteen years, was again used and found to be perfectly efficacious. Unless air is entirely excluded from the apparatus during the inhalation, the time in which anaesthesia can be induced will be unnecessarily prolonged, if not resulting in complete failure, and the patient will exhibit the phenomena of the preliminary stage of improper etherization. The pneumatic face piece should not be too tensely inflated; this will permit of better coaptation to the face. If the patient has a beard, the mask may be moistened around its edges and firmly held against the face, at the same time clasping it on each side of the bridge of the nose. These devices will effectually prevent the entrance of air. The direct air valve should be closed, permitting the gas to expel all air from the tube leading from the gas bag to the inhaler. By folding the gas bag compactly before tapping the cylinder, a dilution of the gas with air will be avoided. The clothing of the patient should be loose; corsets should be removed; in fact, everything which is in the least likely to impede respiration should be avoided. The patient may be sitting or recumbent, whichever is most convenient to the operator. Assurance should be given the patient by telling him how safe the gas is, and what sensations he will experience. He should be permitted to breathe plain air first; this will encourage confidence, and, what is of more importance, will indicate by the clicking sound of the valves whether the mask is properly adjusted.

Perfect quiet should be enjoined, as talking and noises are apt to attract the patient's attention, and no one but the anæsthetist and always a third person, preferably the surgeon or nurse, should be present while the patient is taking the gas. In operations inside the mouth a soft-rubber cube should be inserted between the teeth, so that if tonic spasms of the muscles of the lower jaw occur it will not unnecessarily delay the operation. While the patient should be encouraged to breathe deeply, he does so unconsciously after the first few inspirations, for as soon as pure nitrous oxide is inhaled a deficiency of oxygen in the blood takes place. This venosity stimulates the respiratory and vasomotor centres in the medulla to increased action.

The following phenomena manifest themselves during the inhalation of laughing gas: After the first inspirations the patient begins to experience the usually very pleasant sensations of the gas, nitrous oxide having much the same sweetish taste or odor as chloroform; it has, however, not the irritating effects of chloroform and ether upon the upper air-passages. There may be a slight feeling of suffocation which quickly passes off; a feeling of stimulation is experienced; a tingling sensation of the whole body, particularly in the toes, fingers, and tip of the tongue; a buzzing in the ears; sometimes the patient has dreams of a pleasant or unpleasant nature; respiration is increased in both rate and volume, inspiration being prolonged; the pulse is full and usually rapid (it may be irregular; this does not call for a discontinuance of the inhalation, neither does dilatation of the pupils, which may or may not occur); the face is flushed and phonation may occur; the patient now becomes unconscious (in from thirty to sixty seconds). The reflexes are not abolished, and it is not wise now to test for them, as this may bring the patient back to consciousness. Spasms of the muscles occur; the eyelids twitch and open and close rapidly; the eyeballs protrude or become fixed or oscillate, roll upward or inward; the pupil usually, though not always, dilates. This, with the conjunctival or corneal and ciliary re-

![Image](http://example.com/american-nitrous-oxide-inhalating-apparatus-fig-2.png)
flexes, which may or may not be abolished, is not a safe guide to anaesthesia. Muscular spasms of the face, thorax, abdomen, and extremities occur, stertor ensues, and the face and mucous membranes become progressively more congested until they assume a livid or intensely cyanotic hue. The patient is flaccid, anaesthesia is complete (total time consumed, from one to two minutes). Anaesthesia by nitrous oxide, if properly conducted, is complete from one to two minutes. The available anaesthesia for surgical purposes continues from thirty to ninety seconds. This can sometimes be prolonged by preventing the too rapid admission of oxygen.

After removing the inhaler consciousness returns almost immediately (evidenced by absence of stertor, disappearance of cyanosis, and regular respiration), but the effects of the gas may not entirely disappear for some minutes.

Muscular relaxation may not be complete, and a moderate amount of cyanosis may be persisted in to produce it, though this symptom should always be taken as an indication for the admission of air. If cyanosis is persisted in, the breathing becomes more rapid, shallow, or labored, and the pulse weak and irregular. If oxygen is not quickly admitted, death by asphyxia will occur. As soon as the mask is removed or air admitted, the color changes and stertor ceases. If it is desirable to prolong the anaesthesia, the gas may now be readmitted. In this way anaesthesia by nitrous oxide may be indefinitely prolonged.

The patient should not be permitted to regain complete consciousness before readmitting the gas, and during the second and subsequent application of the mask anaesthesia is more quickly induced than during the primary inhalation.

Nitrous oxide produces its effects principally by the prevention of the admission of oxygen into the blood (a process of asphyxiation, the symptoms of which are indicated by the intense cyanosis); in this condition the respiratory and vasomotor centres are first stimulated, then paralyzed, which is evidenced by the convulsive movements of respiration, arterial contraction, increase of blood pressure, venous engorgement, and engorgement of the right heart. Death occurs from paralysis of the respiratory centre, the heart continuing to beat after respiration ceases. The dangerous symptoms are those principally connected with respiration, and the treatment should consist in the removal of all obstructions to the free ingress of air, artificial respiration, venesection, and possibly tracheotomy; but even in threatening cases these procedures will very rarely become necessary—in fact, the patient regains consciousness before one can carry them into effect. After-effects of nitrous oxide are rare; occasionally there are vertigo, nausea, headache, or a dull feeling about the head; vomiting is an extremely rare occurrence. Glycosuria rarely occurs. I have seen it in three cases in which anaesthesia was prolonged. This disappeared in all cases in a few days, and was probably due to the stimulation of the diabetic centre, which is known to be in proximity to the respiratory and vasomotor centres, and is probably owing to the deficiency of oxygen rather than to an excess of nitrous oxide. Why sugar appears in some cases, though very exceptionally, and not in others, there is at present no satisfactory explanation. After repeated inhalations of pure nitrous-oxide gas on five successive days, I was unable to detect sugar in my own urine.

Many attempts have been made from time to time to eliminate the asphyxial phenomena of nitrous oxide, and these attempts, at the hands of different investigators, have met with more or less success. Bert, of Paris, first used a mixture of nitrous oxide and oxygen, in the proportion of eighty-five to fifteen, with an additional barometric pressure of seventeen centimetres. For this purpose he devised an air-tight chamber with which, by means of pumps, he was enabled to increase the pressure at will. It was subsequently determined by Martin, with Bert’s apparatus, that twelve per cent. of oxygen and an additional pressure of two atmospheres produced most ideal results. This apparatus, while entirely satisfactory, was not practicable and quickly fell into disuse. Bert then sought for a method of producing surgical anaesthesia by laughing gas and oxygen at normal pressure, and used the gas and oxygen with unsatisfactory results. He then used a mixture of nitrous oxide and oxygen preceded by pure nitrous oxide with a satisfactory anaesthesia in the dog for half an hour.

Dr. Hillischer, a Vienna dentist, was the first to practically use laughing gas and oxygen, which he administered in thousands of cases, using first a gasometer and subsequently a regulating apparatus. Dr. Hewitt, of London, after very extended experiments, came to the conclusion that a mixture of laughing gas and oxygen, the oxygen being present to the extent of ten or twelve per cent., answered best in the majority of cases, and he states that there is no definite percentage of oxygen which will answer satisfactorily in every case; that to attain the best results a regulating apparatus is necessary. Dr. Van Arsdale (American Journal of the Medical Sciences, 1891, vol. c) used the gas and oxygen in different proportions. When fifteen per cent. of oxygen was used, the patients exhibited marked muscular rigidity and semiconsciousness; with ten per cent. of oxygen and a moderate amount of pressure upon the gas bag anaesthesia was produced without any cyanosis. His results are practically the same as Hewitt’s, when ten per cent. of oxygen was administered from a distended bag.

My own method of using laughing gas and oxygens has been rather crude, though perfectly effective. I used two cylinders—one of nitrous oxide, the other of oxygen; the rubber tubing connecting the gas cylinder with the reservoir bag was separated in the centre, and a T-
shaped connection inserted; this was connected with the oxygen cylinder, which was opened slightly, permitting oxygen to pass to the bag through the gas tube. I regulated the amount of oxygen with pressure of the foot on the tubing; the bag was first almost filled with gas and then the oxygen permitted to flow in until it was tense. I was not able to determine the exact proportions used in each case, but it must have been in the neighborhood of ten per cent. of oxygen; the patient was then permitted to inhale the mixed gases, each of which was increased or decreased, according to the effects produced on the patient, by permitting more or less oxygen or nitrous oxide, respectively, to pass into the bag. Anesthesia was continued as long as forty minutes in some cases, with entire absence of cyanosis, though muscular rigidity sometimes persisted.

I have discarded this method for the more perfect and satisfactory apparatus of Dr. Hewitt. This consists of face piece, stopcock with valves, mixing chamber of the two gases, and indicator; double India-rubber bag joined together, separated by a septum; India-rubber tubing, one tube being inside the other, for the purpose of conducting the gases from the cylinders; combined stand and union, two nitrous-oxide cylinders, and one oxygen cylinder.

Even greater skill is required in the administration of nitrous-oxide gas and oxygen than in administering laughing gas alone. In ordinary laughing-gas narcoses pure nitrous oxide is used, after which the patient is permitted to breathe ordinary atmospheric air. This, as is known, is nothing but practically diluted oxygen, and can be used only for intermittent administration with the gas. Therefore, by using pure oxygen in a proportion of from eight to twelve per cent., according to the particular types of patients, with a regulating apparatus, it is perfectly possible to induce and maintain ideal surgical anesthesia. The whole principle upon which the mixed gases are used is to give just sufficient oxygen to prevent asphyxiial phenomena and little enough not to interfere with anesthesia. While this principle is easily enunciated, it requires the greatest skill to carry it out. It can readily be seen why the use of the mixed gases in certain known proportions will not meet with satisfaction in all cases. In fact, the proportion of the two gases must be varied from time to time in the same patient, and for this reason a regulating apparatus must be employed.

When using the mixed gases it is even of more importance to exclude all atmospheric air than when using pure nitrous oxide. Sudden transitions from oxygen to laughing gas, and vice versa, are undesirable. The inhalation should be begun with laughing gas and a small percentage of oxygen—two, three, or four per cent.—and gradually increasing the percentage up to eight or ten per cent., avoiding the excitement due to too much oxygen on the one hand and the asphyxiial phenomena of too much nitrous oxide on the other.

The preparation of the patients should be the same as when using any anesthetic. The inhalation, when properly conducted, will eliminate largely if not entirely the unpleasant features of the gas when used alone. The time required to induce anesthesia is slightly longer, taking from three to five minutes, than when using the gas by itself. Consciousness returns almost immediately.

The use of laughing gas as a preliminary to ether is certainly a superb method of anesthetization. It is difficult to understand why it is not more commonly used in this country, as the advantages gained from the patient’s, surgeon’s, and anesthetist’s standpoints more than compensate for the additional apparatus necessary. The advantage is the absence of any unpleasant excitement and irritation due to ether—in fact, there are no stages to the anesthetic; the patient simply quickly and quietly goes to sleep. The anesthesia is induced more rapidly than with chloroform, the time varying, accord-
operation. The quantity of ether necessary to induce anaesthesia will be found surprisingly small, and the unpleasant sequelæ following narcosis will consequently be lessened.

Two different plans may be employed: First, using the gas to complete anaesthesia, and then replacing it quickly with ether in a closed inhaler, accomplished with the American apparatus. Second, using the gas with progressively large quantities of ether until anaesthesia is complete, and then discontinuing the use of the gas. This is accomplished without change of inhalers; for this purpose the Clover-Hewitt (English) apparatus is preferable. At the same time this permits of the use of the gas bag as a supplemental air bag into which the patient breathes.

The indications for the use of nitrous oxide and ether are those for ether in general; the combination should not be given where high arterial tension is undesirable, or in alcoholism and drug habits. Here chloroform will be found preferable as a preliminary to ether.

The inhalation should be conducted, in general, as when giving nitrous oxide alone, and when the patient is etherised the same care is essential as if the gas had not been used. Nitrous oxide does not in any way lessen the dangerous action of ether when used in conjunction with it.

THE NEW INDUSTRIAL POSITION OF WOMAN
IN ITS
RELATION TO HEALTH AND VIGOR.*

By MARY JORDAN FINLEY, M.D.

The new woman may be a myth, but the new industrial place of woman is a reality. Every field of labor is now open to both sexes on nearly equal terms. Women enter business in every branch in all its ramifications. They are finding in learning, in literature, and in work not only the means of supporting life, but the happiness that makes life worth supporting.

To be a happy wife and mother will always be the highest ideal for every good woman; as it ought to be the highest ideal of every good man to be a happy husband and father. But marriage and motherhood are not all of a woman’s life, just as marriage and fatherhood are not all of a man’s life.

The permanency of this change is assured by the fact that it is primarily an economic one. Its coming has not been accelerated by the female shirkers for women’s rights; it will not be retarded by the male howlers for woman’s sphere.

It is the result of the specialism which characterizes the civilization of this age. Skilled labor, complicated machinery, and new motive powers have taken the work formerly done in the home and divided it among many special industries, each carried on most successfully in large establishments.

It is the overthrow of household industries in competition with specialized manufactures that has forced women into the general industrial field. Steam and electricity, which have revolutionized economic conditions, are revolutionizing the social fabric. A recognition of its economic character is necessary to enable us to appreciate the irrevocableness of the change which is taking place—a change which, once fully inaugurated, must affect in some measure all the relations of life.

By it women are placed in a new environment, to be wrought upon by new influences, mental, moral, and physical. As physicians we are deeply interested in the effect which these changed conditions are likely to have upon the health of women and on the strength and vigor of the race.

Pessimists have bewailed the disadvantages of the new activities—the exposure incidental to many employments, the strain of competition in business and labor, the mental application necessary to success, and so on. Let us see if there are not compensating advantages, which give us reason to hope for a more vigorous womanhood, with a progeny less numerous, perhaps, but better bred. In the passing régime are many things that could not fail to be detrimental to mental and physical well-being.

Indoor life is enervating; idleness and aimlessness are not conducive to health. Uncongenial employment is depressing mentally and physically to either man or woman. To oversee a modern household of the well-to-do, or to accomplish all the work of the poorer, is enough to employ well one woman in a family and no more.

That every woman should like housework is no more to be expected than that every man should like farming.

The financial dependence of the sex, assumed in all cases, real in the majority, has entailed an amount of annoyance, chagrin, humiliation, and suffering that has contributed largely to nerve tire, hysteria, and lowered vital tone. No matter what her inherited means or how much work she did in the home, the woman has been considered dependent on the man, who is the head of the family, be he husband, father, brother, or son.

By the wife and children well beloved this was perhaps never felt, but to the unloved wife with unwelcome children, to the widowed daughter, the sister, the mother, the old-maid aunt, the mother-in-law, it became too often the bread of bitterness.

When the woman’s living and social place depended on being loved, the winning of affection and holding it became the most important thing in life. To please some man and keep him pleased was a task which often gave her more care and anxiety than would be required to conduct a large business enterprise.

Fear, envy, jealousy, anger, grief, and all the de-

* Read before the Ohio State Medical Society, May 11, 1899.
pressing passions of "this little fiery-colored world" were bred in her with no outside interests to turn her thoughts in healthier channels. The emotional was cultivated to the general detriment.

If she failed to win or keep love she must look to pity for a living, and to gain sympathy she would exaggerate her little ills to mysterious illnesses until she herself believed in them. What wonder if she became the hysterical mother of defective daughters!

The social necessity of marriage forced women into uncongenial unions, which brought unhappiness and consequent lowered vitality to both parties thereto. It led to marriage with men who were morally and physically unfit to be husbands and fathers. It induced an undue preponderance of the sex element in the life of women.

The idea that man is the unit of humanity and woman the complement to a part of his nature; that she exists only for his happiness and the reproduction of the species, dominating society under conditions that imposed idleness or a narrow range of duties on women, has led to a morbid sex-consciousness in both men and women, and an overstimulation of the emotions and affections in women.

The normal equilibrium between physical, mental, and moral has been disturbed, to the detriment of the entire organism.

Women have been taught in the family relations to yield their will, to see their opinions disregarded and their judgment set aside. The tendency of this has been to weaken the will and to render the judgment vacillating.

It is impossible to foresee how far-reaching may be the social effects of the economic revolution, but it is already evident that these things are changing for the better. Industrial self-support brings with it social independence. The mental stress to which women are subjected in industrial pursuits is such as to tax thought rather than feeling, to develop strength rather than induce weakness. The trouble has long been that women thought too little and felt too much.

Business life cultivates the judgment, the will, the reasoning faculty. It requires self-control and tends to correct the predominance of the emotional nature. It brings a desire for respect and admiration rather than for love or pity.

Higher education gives more healthful mental discipline and a broader horizon with more varied sources of happiness. Diversified interests distract the mind from injurious indulgence in grief, from the exaggeration of trifles, from hypochondria and hysteria.

Wider intelligence and better business methods employed in housekeeping, in the choice and preparation of foods, and in the care of children must be of incalculable advantage to the family.

The exigencies of an active life will require more healthful dressing, at least for business hours. Women will be more out of doors. The girl who goes only twice a day to and from an office or a shop gets at least that much more outdoor life than the one who spends all day in housework; gets that much more exercise than the one who spends the day at home sewing; gets that much more change of sights and sounds to take her out of herself and to give a healthful stimulus to the nervous centres.

Able to choose from a greater variety of pursuits, each may find some occupation in which she can take pleasure and interest.

Managing her own estate or paid for her work, she will not be subjected to the irritation of begging for her own.

When marriage is no longer necessary as a means to gain a livelihood or to escape odium, it will become more an equal pairing, with common interests, and equal rights, duties, and responsibilities. The independence thereby secured to woman in the marriage relation will be one of the strongest possible safeguards for her own health and the health and vigor of her offspring.

The double standard of morals by which we measure men and women is responsible for many suffering women, feeble children, and childless wives. When the economic independence of the sex is fully assured they can demand of men with whom they marry the same purity that men demand of women, and in time there may come a single code of morals by which impure men and impure women, alike debarred from marriage, may herd together outside the bounds of decency, unlikely to perpetuate their kind.

I have spoken of the new industrial position of the sex. It is not new; it is old as the race. It is a return from artificial to natural conditions. Throughout Nature the struggle for existence engages equally male and female. Among all primitive people women have borne an equal share in the battle of life. Agriculture and manufactures, as well as the preparation of food, were women's work among the Indians. The peasant women of Continental Europe work in the fields side by side with the men, and in Vienna many of us have seen them digging sewers and carrying the hod up the walls of buildings that rival those of Chicago in height.

Generations of toil have given to those women a powerful muscular development. The patients in the gynecological clinics did not come from that class.

Something of moral refinement, something of physical charm, women may have gained by being relieved from the racial struggle, but they have lost in development of mental and physical strength. The home is woman's sphere, we are told; but with all the varied activities that once centred there taken out of it, except the last steps in the preparation of food and the promotion of cleanliness, it becomes too narrow, monotonous, and aimless, it affords too little of either mental stimulus or muscular activity. Kept within it, the woman's
thoughts, interests, and sources of happiness become too much centred in her sex relations, her position as wife, mother, or maid.

Social conditions which have tended to specialize the human female as a merely reproductive organism have not produced a vigorous womanhood.

I am convinced that the causes of the peculiar susceptibility of our women to pelvic disease is to be found not in the individual, but in racial degeneracy, the result of an artificial condition of society, a faulty environment, leading to perverted innervation and tropic change. Imperfectly functioning pelvic organs are stigmata of degeneration, if you will.

Women need a new environment. They need to be wrought upon by new influences which will stimulate equally and tend to develop symmetrically all the faculties of the mind, all the functions of the body. Such an environment they will find in the world of work which is now opening to them, such influences in its imperative demands.

MY OBSERVATIONS
ON THE TYPHOID-FEVER EPIDEMIC
IN SOUTHERN CAMPS,
AND ITS TREATMENT.

By JOSEPH F. CHMELIEK, M.D.,
LATE ACTING ASSISTANT SURGEON, U. S. A.

It will be necessary to describe briefly the conditions prevailing upon my arrival at Tampa, Florida, August 3, 1898. At this time the authorities in Washington realized the peril to which the troops were exposed if left in a through-and-through infected camp. The troops that were left behind after the last expedition started for Puerto Rico received orders to move farther north, either to Jacksonville or Fernandina; consequently, all the regimental hospitals suddenly left behind in succession from twenty-five to forty-six patients, who had to be accommodated in the Second Division Hospital of the Fourth Army Corps. To this hospital, which, although it had been opened only three days, contained a hundred and seventy-six patients, it was my fortune to be assigned upon my arrival in Tampa.

There was but one assistant surgeon, who was sick himself, to take care of this great number of patients, and he was almost helpless from the lack of medicines, nurses, and orderlies.

The hospital proper, a brick building situated on the flat land at West Tampa, had been previously used as a convent, and was admirably adapted for hospital use, being provided with a large number of windows and several entrances. It had three floors, and the floor space of each was about ten thousand square feet. On the ground floor were a small room used as an office, and a separate room as an officers' private room, with two other rooms of about equal area, one of which was used for preparing patients for admission, and the other as Ward No. 1.

On the second floor were three rooms divided into two wards, and the entire top floor, consisting of one large, light hall, was used as the fourth ward. Besides this, there were several tents used as isolation wards for measles cases, and convalescent wards composed of about a dozen hospital tents.

To inspect and examine a hundred and seventy-six patients, with the outside temperature at 105° F. in the shade, and with thousands of flies keeping one company, was not a very pleasant task, but it was very interesting work. Patients with typhoid fever, malarial fever, dysentery, plain diarrhea, venereal diseases, and even suspected cases of yellow fever, massed together, constituted a chaos not soon to be forgotten.

After two hours of hard work inside, we emerged to inspect the grounds, kitchen, pits, etc., and accidentally stopped to look at the process of filtering water used for drinking purposes, when the chief surgeon took the dipper from the receptacle filled with boiled and filtered water, took a good drink, explaining the harmlessness of such water (which came from an artesian well only forty feet deep, and through loose sand), and deposited the same dipper back into the vessel. This oversight cost me much trouble with the hospital-corps men, who witnessed it and naturally tried to do exactly the same thing as they had seen the chief surgeon do—viz., drink from a dipper and deposit it back from their lips into the filtered water. I must add that a good-sized lump of ice was placed occasionally in this water to keep it cool.

The pits were only about forty feet from the entrance to the kitchen tent, and the number of flies around these holes was countless. Although the camp police had orders to cover these pits occasionally with sand and lime, they avoided the work as much as possible, and it required my colleague's and my own constant attention to see that it was done at least every three hours. In addition to the pits there were two large barrels—one filled with strong bichloride solution, in which all the sheets were dipped before being sent to the laundry, and the other used for washing out bedpans and receptacles from the hospital. Except for the absence of some minor articles, as cuspidors and spit cups, the sanitary conditions were fair.

This could not be said about the food. Although the Red Cross Society was well represented by the head nurse, Mrs. Freer, and Dr. Partella, the agent at Tampa, who tried their best, it took nearly fourteen days before we could secure for our patients, especially the convalescents, nourishing food.

Milk, which spoiled within two hours after its receipt, was good when fresh, but it often gave out, and then there was nothing to replace it. The lack of attention caused delay in supplying the sick at regular intervals with milk, and the oatmeal, which was on the
list of light diet, was often unfit to eat, owing to its being burned. All this was remedied later, about the 10th, when almost everything was supplied by the Red Cross Society. After the appointment of a United States army surgeon as chief surgeon, the requisitions for medical supplies were promptly attended to.

Having taken charge, I endeavored to introduce some system, and recommended therefore to the chief surgeon that the serious cases of typhoid should be separated and placed in one ward, the surgical in another, etc.; but this request was denied or overlooked, and I had to arrange with my colleague, Acting Assistant Surgeon Cox, to get out of this chaos. We decided to constitute the first and third wards the severe typhoid-fever wards, using the second for mild cases, and leaving the fourth, or the entire top floor, for mild cases of typhoid and malarial fevers and for convalescent patients. This ward we left in charge of a male nurse, with two orderlies for day and two for night service, and concentrated our force of female nurses in the lower wards.

Later, when the patients kept arriving by a score or two a day, new tents were erected on the west side of the main building, where surgical cases and those under observation before being sent on furlough were accommodated.

On August 8th the hospital contained two hundred and twenty-three patients, and up to that date not a death had taken place. On the 9th the staff was changed and a major and surgeon of the United States army took charge.

On the 14th we discharged twenty-five soldiers as cured and lost two, a corporal from the first ward, with haemorrhages and perforation, and a private from the second ward, who died of toxæmia and exhaustion. On the 16th we lost a private in the second ward and a corporal of the Fifth United States Cavalry in the first ward, both from haemorrhages with perforation. The autopsy showed the best specimen of ulcerated intestines I have yet seen. On the 16th another contract surgeon arrived, and now we divided the time so that two surgeons remained always on duty, while the third took half a day off, so as to get a breath of fresh air and finish his charts and reports. On the 18th a hospital-corps man died in the third ward, and the same night and during the following day three more died in the first ward, one of black vomit and one from cerebrospinal meningitis. The excessive rain in the thunderstorms, which occurred each afternoon, blew some of the tents down and exposed many patients, but without ill consequences. By this time, the 24th of August, four hundred and eighty patients had been treated with only eleven deaths, although a large number had complications. On the 26th a trainload of convalescents, ninety-six in number, was sent north, and only twenty-four were left behind. The heat and moisture at this time were intense; and it was a great relief for the patients to be sent to a cooler region. The working staff consisted of one hospital steward, three acting hospital stewards, forty-four hospital-corps men, nine female, and one male nurse, and three acting assistant surgeons, besides the chief surgeon and executive officer.

The patients consisted mostly of cavalrmen, except the measles cases, which all came from the Second Georgia, United States Volunteers. The First United States Volunteer Cavalry and the Fifth and Sixth United States Cavalry were represented in the largest numbers. There were many from other regiments and from the hospital corps among the sick, but they all suffered with more or less severe intestinal disorders and malarial fevers, except the hospital-corps men, who suffered from typhoid fever, contracted while on duty. The majority were regulars. In Fernandina exactly the same conditions prevailed. On September 1st, the night when the Olivette was sunk, we arrived to take the place of the volunteer surgeons and to bring out order from chaos. Some regimental surgeons would not consent to the removal of their patients to the division hospital, but insisted on keeping them in the regiment with all the disadvantages attendant thereon, in order to be able to try their own particular treatment, and, as the troops were moving on to Huntsville and elsewhere, many patients were left behind, filling the division hospital to its fullest capacity. No lack of surgeons prevailed, but the hospital-corps men, being all volunteers, were badly trained—a lot of spoiled babies who expected to have a sort of picnic when they enlisted, and whose colonels, in many instances being tired of the many charges preferred against them, and yielding to influence at home, assigned them to the hospital corps in order to get rid of them. They were absolutely valueless as help to a surgeon, or as nurses, and were unwilling even to offer a drink of water to the patients. With regard to the hospital proper, I will quote some sentences from my report made to Chief-Surgeon Carter, United States army, at whose request I made the preliminary examination upon our arrival at this camp.

September 3, 1898.

SIR: I have the honor to report upon the sanitary condition found in the division hospital on our arrival on September 1, 1898, as follows:

1. Location.—The site of the hospital has been inadjudiciously selected for the following reasons:

1. The prevailing wind in summer being the southwest, south, and southeast, it blows from the ocean directly over the entire camp, toward and over the hospital tents.

2. The corral and ambulance stand being located due south from the hospital, the wind brings in all the flies which infest those places.

3. The roads leading to the hospital are of deep sand and stumps, uneven, and in places of such bad condition that shaking and jarring of the patients in the transfer can not be avoided.

4. The distance to the base of supplies and the
trains and the city is a considerable annoyance and a cause of great inconvenience in bringing fresh meat, milk, and other necessaries for the patients, on account of delays.

II. Water Supply and Food.—Although a pipe runs close to the hospital, there is but one faucet from which to draw water, and this is over a hundred paces from the nearest tent. The kegs and barrels containing drinking water were found to be in a filthy condition, full of floating particles of food and sand, and in the immediate vicinity of patients suffering from typhoid fever. The same applies to the milk. The walking and convalescent patients, orderlies, and stewards were in the habit of using their own cups and dipping the same directly into the barrel containing ice water. These barrels were not sterilized or disinfected, or even scalded with hot water for some time, and the contamination could not be avoided.

III. Kitchen.—The kitchen is placed halfway between the hospital and the corrals, the latter holding over eighty mules, and the flies, after worrying the animals and patients on either side, went over the food exposed for a considerable length of time, and vice versa, thereby infecting the kitchen utensils and food used by the patients suffering with malarial fevers and surgical and venereal diseases. The smoke and odor from the kitchen passed directly over the hospital tents.

IV. General Sanitation.—The condition in and about the wards was found to be deplorable. The soiled linen, sheets, pillows, and bedclothing of all descriptions was piled on a heap around every tent for exposure to the sun, and when dried by its rays was dusted out by handling carelessly.

The bedpans and pails used by the patients were left in and about the wards for hours in the hot, broiling sun, and in the immediate vicinity of the barrels containing ice water and milk. The floor was left unprotected by boards or lime, and the patients were allowed to expectorate on the sand-covered ground.

V. Condition of Patients.—The patients were in the most unhygienic condition. Soiled linen was left underneath them. Bedsores were unattended to in sixteen cases, and their mouths and hands were unwashed. Some were lying deep in the poor spring-wire cots, almost upon the bare ground, doubled up, unable to move to either side, and were covered with flies and mosquitoes. Every patient was permitted to order and eat whatever he could obtain, and many were fed on hardtack, others ate fruits, such as oranges and lemons, which were left lying all around their cots and tables. The milk supply was insufficient, some patients obtaining only from two to three ounces twice a day. This deficiency had been partly remedied by giving them lemonade, coffee, and soups, which last alone could be considered nourishment, and was given by the kind-hearted ladies of the city.

VI. Medication.—Almost every patient was given quinine in large dose, some being deaf from its effects. I do not wish to go into details of my criticism of treatment, and therefore refrain from making a full report on this particular point.

Respectfully submitted, etc.

I can not pass this subject by without attempting to place the responsibility for this state of affairs where it properly belongs. That there was an unfortunate mistake committed in mustering in volunteer regiments intact is generally understood to-day, and every volunteer soldier will tell you why. But that the surgeon-general was deprived of the power to examine and select his own subordinates, who had the health of the troops and the lives of the patients in their charge, is beyond conception. The majority of the regimental volunteer surgeons were young and incompetent for field service, and the surgeons in charge, although able and willing, could not overcome this defect. The blame belongs to Congress, which passed the law.

The major, seeing that to keep the sick at such an infected locality would be wrong, pitched camp on the beach to the east of the Strathmore Hotel, and the patients were transferred to the old dancing pavilion, from which a beautiful view was obtainable over the Atlantic Ocean. This pavilion accommodated comfortably a hundred patients.

The change was made in such a way that those whose condition permitted of transfer were loaded with their own cots into an army ambulance, and one by one were carried to a beach nearly four miles distant without accident or mishap. In all, a hundred and six patients were thus transferred.

The effect of the sudden change from a hot, dirty, fly- and mosquito-infested place to a beach where, in the constantly changing sea breeze, they could enjoy the sight of the waves playing almost at their feet was magical. It exercised upon the patients an influence which only the record can explain. The first two days there was some depression, but in from forty-eight hours to three days all the sick appeared cheerful, their faces resumed a more natural color, and the enormous appetite which was aroused even in the apathetic, whose condition was quite serious, gave encouragement to the attendants and doctors. Some of the sick did not sleep for from ten to fourteen days prior to their removal on account of the mosquitoes. Having been placed by the major in charge of this hospital and assigned for duty from 8 A.M. to 4 P.M., when all the prescribing and orders for food were given, I had an excellent opportunity to exercise my judgment, and to order treatment according to my experience in Tampa. The record of this hospital shows a hundred and seventy-eight patients with not a single death between September 1st and 30th.

The staff consisted of two hospital stewards, United States army, one acting hospital steward, United States army, and about thirty-five volunteer hospital-corps men, eight female and two male nurses, four contract
surgeons, one captain of volunteers as executive officer, and a chief surgeon, with the rank of major, United States army.

The question, What caused the spread of typhoid fever first among the regular troops and among the volunteers? occupied my mind from the first, and I believe that, having paid close attention to everything that was going on around, I can explain why the regular soldier, who usually keeps well under the most trying conditions, and who is accustomed to regular army rations, was affected just as much as the volunteer.

I noticed that the largest number of typhoid-fever cases among the regulars occurred in the cavalrymen. Now, this is not so hard to explain if we take into consideration: 1. That there are always some sporadic cases of typhoid fever about a large encampment. 2. That there are always some cases of typhoid fever in and around Tampa. 3. That the numberless flies that gather around horses find the pit and the kitchen, especially the brown sugar in the kitchen, which stood exposed for hours and was almost black with them, looking more like a bag or box full of raisins than sugar. 4. The natural inclination of soldiers to consume unwholesome food, such as pies and ice cream, which were made and sold by storekeepers regardless of the material and source from which the different ingredients, including the milk, came.

It was impossible to keep the flies from the already cooked food, even if a man kept one hand over it and ate it out of the other. Climatic conditions naturally prostrated the men to some extent, while dissipation, stale beer, and in many cases prolonged diarrhoea, made the men fit subjects for infection. The carelessness of the volunteer officers, who, instead of setting the privates a good example, were the first offenders, will prove how easily an epidemic may be started; and when it once gets hold of a camp the only remedy is to move that camp, which was done. The proximity of a large city to a military camp does not improve matters. A system run down by nocturnal excesses, dissipation, and probably venereal disease in addition, is liable to get infected very rapidly. The filthy and insanitary condition of the streets and saloons also contributed a great deal to diarrhoeal trouble, which subsequently proved a predisposing cause, and to the malaise that usually precedes the fever. It would be a useless encroachment upon time and space to go into any further description of the many causes that led to the epidemic.

As almost all the cases were alike, the history of one will serve for all, and the treatment I shall sum up once for all in my conclusions. Suffice it to state that the proportion of disease was about seventy-eight per cent. of typhoid fever to twenty-two per cent. of all other diseases combined. Of these last, there were about ten per cent. of malarial fever, six per cent. of dysentery, three per cent. of venereal diseases, and one per cent. of surgical diseases other than venereal. To recapitulate, of the six hundred and fifty-eight cases treated in the two division hospitals, five hundred and thirteen were typhoid fever, or seventy-eight per cent., and the rest as described.

**Symptoms.**—The patients usually complained of diarrhoea for several days, with headache, some depression, weakness, and general discomfort. Quite a number of soldiers kept doing their duty until put on guard, when they suddenly noticed greater headache, dizziness, and fever, and had to report sick. This lasted from a few days to a week, when they were admitted to the regimental hospital, with loss of appetite, general confusion of ideas, and inability to stand upon their feet. There the surgeon found the fever to be from 102° to 104° F., with some enlargement of the spleen, meteorism, and the characteristic rosy spots (which, by the way, were present in almost ninety per cent.). The majority of the cases were transferred to the division hospital at once, so that we had only very little difficulty in making and corroborating the diagnosis of typhoid. In only a dozen or so of cases I had the opportunity to try the diazo reaction with my private supply of reagents until that gave out, when, as no fresh supplies were on hand, and not having even a microscope, the Widal test had to be abandoned.

The diazo reaction failed only once, and I believe that was on account of complication with malarial fever, and the fact that the length of the fever could not be determined accurately, the patient having been admitted to the regimental hospital on July 17th and treated with large doses of quinine for malaria to the extent of causing deafness, while he had all the symptoms of typhoid fever well marked on the 7th of August at his admission to the division hospital. The test took place on the 12th, almost a month from the beginning of his sickness.

The complications encountered were in the order named as follows: Diarrhoea in the great majority; simple tympanites in one hundred and ninety-eight cases, or 38.6 per cent.; extensive tympanites, with abdominal pain, in thirty-seven cases, or 7.2 per cent.; intestinal haemorrhages in forty-two cases, giving eight per cent., four of which cases proved fatal; cerebral symptoms—e. g., delirium, apathy, and coma vigil—in thirty-one cases, or six per cent.; muscular prostration and tremors in twenty-nine cases, or 5.6 per cent.; meningitis, with toxemia, in two (both proving fatal), or 0.39 per cent.; pneumonia in four (of which one was fatal, from blood clot in the heart cavity); intestinal perforation in three cases (all fatal); parotiditis in one case, and alveolar abscess in one; furunculosis on the face in one—total, five hundred and thirteen cases of typhoid, with eleven deaths, the death-rate being 2.19 per cent.

It will be interesting to explain here that those addicted to alcohol suffered mostly from delirium and cerebral symptoms, while those addicted to the smoking of cigarettes suffered more from toxemia, muscular
prostration, and tymanites, with pain. These last named usually suffered relapse more than all other cases combined. In one particular case relapse was caused by half a dozen molasses candies eaten the fifth week of the sickness, when the patient was for one week convalescent. Sixteen cases of bedsores in the Fernandina camp developed prior to our arrival. As to the treatment of typhoid fever, I must say that in view of this remarkable record I have no explanation to make without going over the list of cases and giving each individual case treated separate consideration. This being impossible, I may state that the physician who undertakes the treatment of typhoid fever must have three main objects in view: 1. To treat every individual case according to the symptoms. 2. To study his case closely, and to find out if possible in the first forty-eight hours what kind of food the patient can assimilate. 3. To treat each case in the open air, with a trained nurse as his assistant, and with as little medicine as possible.

I. The patient should be put to bed at once and made comfortable. A hard bed with a water mattress is the best. Do not allow your patient to sink in a lot of feathers. Give him a bath and put him strictly on milk diet. There are no means to check or stop the course of typhoid fever, notwithstanding the assertion of many to the contrary, by internal medicines after the poison has once gained entrance into the system.

Whenever the temperature reaches 102° F., give a sponge bath; if it should reach 103° F., give a bath, and if still higher, rub a lump of ice over a wet towel applied to the chest and abdomen until the temperature is reduced. Adopt the Brand method as to baths. Patients like it after they get used to it, and will demand it whenever they feel uncomfortably warm. The benefit of the cold bath can be judged by the amount of urine excreted soon after. If too depressing, add alcohol to the bath and give half an ounce of brandy while in the bath tub. The diarrhea is best controlled by the time-and-again-tried remedies, bismuth and salol. Give two grammes (thirty grains) of the former to five decigrammes (or eight grains) of the latter. I obtained excellent results from three doses in twenty-four hours.

II. I have seen patients dosed with all possible so-called intestinal antiseptics die in spite of all the heroic efforts to keep them alive, because the surgeon made it a routine business to give milk or lemonade to every patient. Now this is a serious question to consider. I will quote a few cases from my experience.

Case I.—B. H. R., private, Troop II, Fifth Cavalry. Third week of typhoid fever, some tymanites, increased always after ingestion of milk. Stools very offensive, showing eruds of undigested milk. Tried peptonized milk with the same results, also beef broth, milled milk, and beef juice without material improvement. Finally gave him a cup of chicken soup, which he took with great appetite, and he was subsequently kept on this diet for three weeks to complete recovery.

Case II.—J. L., private, Troop A, Sixth Cavalry, same as preceding. This patient got well on liquid peptonoides.

Case III.—C. M., private, Troop II, Fifth Cavalry, same as foregoing. He vomited on seeing milk, but got well on beef juice in ice water, and later on imperial granum.

Case IV.—G. J. K., private, Company E, Fifth Ohio Volunteer Infantry, could keep nothing on his stomach, but had a great desire for an egg. As a matter of experiment I allowed him the egg. To my surprise, he kept it down, assimilated it without any rise in temperature or uncomfortable abdominal symptoms, and from that time on was kept on three eggs a day.

I could cite many cases of a similar character in support of my assertion that the first duty of the attending physician is to select food which will be easily assimilated, but I believe these four are sufficient.

III. It is absolutely necessary to have a trained nurse for day and one for night service, as complications arise very rapidly, and a fatal termination may take place without any forewarning.

I may here cite the case of an acting assistant surgeon, United States army. At 5 p.m. he felt better than on any previous day except as regarded the constant abdominal pain and slight tympanites. At 7 p.m. his temperature suddenly dropped below normal, his pulse rose to 150, and, although his condition was discovered at once, he died of septic peritonitis with perforation within five hours. Now, suppose that he had been left alone—he might have died much sooner, without anybody being able to give him any assistance whatever, as he was supported during those five hours solely by hypodermic stimulation.

The open-air treatment has been given the severest of trials, and has proved so effective that it can not be overlooked. The removal of patients in every condition and stage (except the hemorrhagic) of typhoid fever for a distance of nearly four miles without a single loss, and with such remarkably rapid improvement in their general condition, must appeal to everybody for a trial.

Very little medicine, except for complications, is necessary for a typhoid-fever patient if the case is properly managed from the beginning. Stimulants should be resorted to from the beginning of the third week, brandy in three-drachm doses with four ounces of milk every three hours being about right. Later, a thirtieth of a grain of strychnine three times a day in addition goes far to make the patient throw off the typhoid-fever tongue. It may be given with the addition of fifteen drops of diluted hydrochloric acid.

In the treatment of complications I have already mentioned bismuth and salol as the best anti diarrheal agents.

The next in the line of frequency is the treatment of hemorrhages. I ordered an ice-bag filled with finely cracked ice, and renewed every twenty minutes, to the abdomen; and five drops of aromatic sulphuric acid in water. If the hemorrhages were profuse, I added
sixty minims of fluid extract of ergot and gave about a quarter of a grain of morphine hypodermically. The raising of the foot of the bed or cot, and even bandaging the limbs, should be resorted to in order to keep the heart going. Transfusion of salt water was also used, as was enteroclysis with normal salt solution. Cases in which tympanites occurs without pain do well on fifteen drops of turpentine and a turpentine sup, but in no case of tympanites with pain should turpentine be used internally. Salol and bismuth, or guaiacol carbonate with bismuth in capsules, with laevage, and probably the passing of a rectal tube high up, as well as abdominal stupes with turpentine, will all be good agents to try, but you should always be on the lookout for perforation in this undesirable complication. For the cerebral symptoms, the ice-bag, general baths, and small doses of phenacetine are sufficient. In no case resort to opium. The muscular prostration can be overcome by alcoholic sponge baths with small doses of strychnine or tincture of nux vomica in water.

I have witnessed failures from the following remedies: The Woodbridge treatment; the iodo-phenol treatment; the indiscriminate dosing with quinine or calomel in abortive doses. The sulphoboracates have failed in many cases, and the exclusive turpentine treatment has even proved fatal.

I came to the following conclusions:
1. The camp should be frequently changed.
2. The division hospital is here to stay, as only in this hospital can female nurses be employed, and
3. The proper person as attendant is the female nurse.
4. All soldiers should be educated in plain sanitary hygiene.
5. The sooner the patient takes to bed the fewer complications are likely to follow. The hemorrhagic and perforation complications develop in patients who walk until they fall and who use indigestible food during the first stages of typhoid.
6. Milk is not suitable for every case; many of the patent foods on the market, especially “predigested” foods, must replace it in many cases.
7. Sugar used during convalescence will cause relapse quicker than solid food.
8. Every case requires special study.
9. The severest case, with hemorrhages and other complications, may get well, while the lightest case, apparently doing well, may prove fatal. Never give up a case as hopeless.
10. All the patients in the southern camps showed a remarkably low pulse rate even with high temperature, for which I can not offer any explanation.

Through the courtesy of Dr. L. H. Gilham, of Kolso, Tennessee, I was permitted to operate in the following, in many respects, remarkable case:

Beulah H., aged twelve years; daughter of a farmer. Healthy until symptoms of present trouble began, about a year ago. Although the symptoms had been present for about a year no importance had been attached to them, and no physician had been asked to see her until one week before I saw her. When Dr. Gilham saw her he was told that she had an enlarged tonsil. Upon examination he found it to be a nasal polypus, the lower end of which was protruding half an inch below the margin of the velum pendulum palati. The right naris was filled with a polypus and the left was so obstructed by the polypus lying in the nasopharynx that she could get no breath through it. The left middle turbinate was also very greatly enlarged because of the inflamed condition of the mu cosa covering it. Breathing was effected entirely through the mouth.

When I was asked to see her, one week later, I found her in substantially the same condition as described above, and with the assistance of Dr. Gilham, at their house, at once removed the growth by avulsion manually.

The nostril was so filled with the growth that it was impossible to pass the snare wire, and the growth was so large it could not have been withdrawn through the nose even had its base been severed by the wire. After spraying the nose and nasopharynx with cocaine, I fastened a tenaculum into the posterior surface of the pharyngeal portion of the growth and drew it downward and forward as far as possible, and grasped it with a heavy dressing forceps, but was unable, owing to the large size of the tumor and the location of the pedicle, to twist it off. I then pulled it out as far as I could, as before, and passed my fingers behind the tumor into the nasopharynx to the posterior nares, grasping the tumor firmly. I found it attached to the septum, just at the opening of the right posterior naris, by a pedicle the size of my little finger. Using my finger nail as a knife, and pulling hard on the tumor, I had no trouble in tearing it from its attachments and withdrawing it through the mouth, and with the nasopharyngeal tumor I brought out the one which had filled the right naris and two long, flattened polypi, which I believe to have lain in the nasopharyngeal space above and posterior to the large tumor. There was but little hemorrhage, and the relief was very marked and immediate.

One week after the operation the inflammatory swelling of the right middle turbinate had subsided and the cure seemed perfect.

The body of the polypus, measured from the nasal to the pharyngeal extremities, was three inches and a quarter long; an inch and a quarter wide at the widest part, and seven eighths of an inch thick at the thickest part. It weighed, fresh, one ounce avoirdupois. It was nearly a pure myxoma. The anterior surface of the pharyngeal portion was roughened by the impact of
food against it during deglutition. The smaller polypi measured an inch and a half long, but were very slender and flattened, as if they had been subjected to much pressure. The nasal lobe was large and filled completely the right naris, and had caused considerable external deformity of the nose by its pressure from within. The four polypi had one pedicle common to all.

There are several remarkable features about this case, chief among which is the extremely large size, age considered.

Wright (1) describes a case in which the tumor—five inches long—projected into the pharynx, but this was in an adult and of twenty years’ standing. He says others have been reported approximating it in size. He remarks also that congenital cases have been observed.

The youngest patient seen by Delavan (2) was thirteen years old. Delavan says, in the same essay, that in two hundred cases reported by Sir Morell Mackenzie, but sixteen patients were under twenty years of age. Holt (3) says “they are especially rare before the seventh year.” Sajous (4) says they are seldom seen in children. Casselberry (5) thinks polypi are only relatively rare in children, “since the diseases which influence their development are somewhat less usual in children than in adults.” He has seen them in children from eight years upward. Vogel (6) has removed a polypus from a child of four. He remarks (loc. cit.) that fibrous polypi may attain such size as to hang down into the pharynx and embarrass respiration and deglutition. While he speaks thus of fibrous polypi, it is well to remember that my case is almost a pure, unmixed myxoma.

As bearing on the size, we may note that James (7) says they may attain such size as to completely obstruct the passages. My case certainly bears out this statement, because the lobe which lay posteriorly so completely filled the nasopharynx that the patient could get no breath through either nostril.

Another feature worthy of notice is the fact that the tumor had its origin from the septum.

“They almost never spring from the septum” (8).

Heinman (9) reports five cases of vascular polypi in patients of from two to fifty years old springing from the septum; these cases, however, differ from my own in being of the vascular type, while my case was almost avascular. Lefferts (10) says “true myxomatous” (as in my own case) “are occasionally encountered springing from the side of the septum.”

Another feature deserving mention is the method of removal—manual avulsion.

While every one to-day recognizes the usefulness of the snare, yet we will occasionally meet with cases not suited to its use, and, as Delavan (11) says, “no one instrument will be likely to meet the requirements of every case,” we must be prepared to deal with the cases as they come, and in the words of Tillmanns (12),

“The use of the forceps seems rougher to be sure, but it is simpler at all events, and accomplishes the object more quickly.” Used with discretion, there is no reason why the forceps should do more harm than the snare.

In conclusion, I may sum up briefly the noticeable features thus:

1. The very large size of the polypus.
2. The age and sex of the patient—only twelve years old and a female.
3. Its origin from the septum nasi.
4. The removal by manual avulsion.

A CASE OF PUERPERAL SEPTICÆMIA.*

BY STEPHEN J. MAHER, M.D.,
NEW HAVEN, CONN.

In the following case the thing that is remarkable is the persistence and intensity of the fever. The temperature was alarmingly high for eight weeks.

On February 2, 1899, I delivered Mrs. M., aged twenty-seven years, a healthy primipara, of a daughter. The labor was normal. There was a slight rupture of the perineum, which was not stitched. On my visit on February 3d I learned, somewhat to my surprise, that the nurse, an untrained woman, innocent of asepsis, had passed a catheter on the patient during the night. I enjoined the necessity of patience and cleanliness. Catheterism was repeated on the second and third days, and then the nurse left to care for another obstetric case. The mother of the patient, an old lady puffing and wheezing with bronchitis, tended the case for twenty-four hours. On the third night the patient did not sleep, and on the fourth day she had a chill. I called in the afternoon, and found a temperature of 103° F., a pulse of 120, headache and backache. There were no local symptoms. The lochia were not offensive. The bowels had been moved with castor oil the day before. I passed a catheter, ordered a vaginal douche of creolin.

* Read before the New Haven Medical Society, April 19, 1899.
a phencetine powder, large doses of quinine, and a calomel purge. I came around again in the evening prepared to enurette the uterus, but the temperature had fallen to 100° F., and the entire absence of tenderness or pain in the abdomen made me postpone the operation. The next day she was deaf from the quinine, and with a temperature of 104.8° F., and very much worse in every way. There was now some pain in passing the stool, and a tender spot in the abdomen close to the pubes and to the left of the median line. I gave her a thorough intra-uterine curetting and douching, and swabbed out the uterus with plain tincture of iodine. Five minutes after I had finished she had a frightful chill, her temperature rose to 105.5° F., and she became almost pulseless. I ordered half an ounce oficed whisky every half hour and drove off after a trained nurse. The story of the rest of the fever is best told by her temperature chart, which I hereby offer as an exhibit.*

The abdominal tenderness disappeared in two days, but it was five weeks before there was the least desire on the part of the patient to pass urine. Of course, she was catheterized regularly. During the first two weeks she was curetted four times and received every day four or five intra-uterine douches. After the second curetting the result of the operation was nil, and the result of the douches was only to make her feel better and to reduce the temperature about a degree. In the third week the involution of the uterus proceeded very rapidly, and the discharge, which at no time had been great, though sometimes pronouncedly purulent in character, ceased entirely. During the second week she had a very copious purulent pharyngeal discharge, which, like the uterine discharge, proved to be practically a pure culture of staphylococci. Spraying menthol in oil into the nose and throat for a few days stopped the trouble in the pharynx. On March 15th, or during the sixth week of the fever, this pus began to form in the pharynx again, to invade her Eustachian tubes and nares, and to cause an exfoliation of the mucous membrane of her mouth and throat. She was too weak to permit of thorough examination of her throat and nose, but so far as I could make it out the discharge was an exudate, not the result of the bursting of an abscess. It required a week of hydrogen peroxide and the menthol solution to clear this up. With the exception of this peculiar discharge from the pharynx, the slight discharge from the uterus, the vesical atony, and the short-lived tenderness over the bladder during the first week, there has been nothing in this case from beginning to end but fever.

What kind of fever was it? The first hope was that it would be malarial. Quinine was tried in large doses and small, in all sorts of ways, but it never had the slightest effect, except to deafen the patient. Examination of the blood for protozoa and other end of the case proved negative. The Widal test was tried with negative result; besides, there was nothing but the temperature chart to suggest typhoid; there was no headache, and there were no ablominal symptoms whatever.

The rapid respirations during a good part of the fever may suggest pulmonary trouble. During the second week and the sixth week there were a few days on which fine moist rales were audible over the bases of both lungs, and on one day during the sixth week there was a slight, painful cough; but at both times these symptoms and signs cleared up on the administration of small doses of digitalis.

Let me again return to that fever. During the first fortnight it averaged 104° F., several times almost reaching 106°, never going below 102°, and for one stretch of a week continuing night and day over 103°. Then came a few days in which there were two brief remissions to 99°, followed in two hours by leaps to 104°. These were succeeded by four long weeks during which the temperature averaged 103°, often going over 105°, and at six scattered half hours frightening me by sudden short drops to 99°. During the final two weeks, although the freaks of that temperature were the cause of much anxiety, the fever was evidently dying out. On April 4th, over eight weeks after the first chill, the temperature became normal and has remained so since. The patient, thank God, is now sitting up, eating beefsteak, but unable to stand, and emotional. When the throat symptoms of the patient were at their height, the nurse, the husband, and the physician, the only ones who had access to the sick-room, were attacked by a vicious little pharyngitis.

A few words as to the treatment: I have spoken of the intra-uterine douches during the first two weeks. During the third and fourth weeks either intra-uterine or vaginal douches were given two or three times a day, and during the night in conjunction with cold sponging or the cold pack, when the temperature reached 105° F. During the first two weeks the bladder was washed out every six hours after every catheterism—sometimes with plain water, sometimes with a weak solution of boric acid. Whenever the temperature reached 104° the cold sponge bath was given, and if the temperature proved obstinate the cold pack was used. On six or seven occasions it was necessary to keep the patient in a cold pack for three and four hours before the temperature dropped to 103°.

One evening the cold packing was begun at eight o'clock and with an intermission of an hour was continued until four o'clock the next morning. As there was no ice in the house that night, snow was used to keep the water cold enough to make an impression on the fever. All during the fever the patient had half an ounce of whisky every two hours; but at times of special stress, as when the pulse became faint and irregular at the height of the exacerbations of fever, and when, just as surely, the pulse disappeared from the wrist during the sudden drops, half an ounce of whisky was given every fifteen minutes. During at least eight days she drank a quart of whisky every twenty-four hours. One sixtieth of a grain of strychnine was given every three hours during the middle four weeks of the sickness, when the heart was weakest. Digitalis was not used except to relieve the setback in the lungs, on the occasion already referred to, and for the worst symptoms of cardiac distress.

During the first five weeks the diet consisted of peptonized milk and milk and lime water. Then lamb and chicken broths were added. The giving of the first egg, March 22d, was followed by a sudden rise of temperature to 104° F., vomiting, and collapse. Whenever the temperature reached 104° the patient vomited, and afterward retained nothing but iced whisky until the thermometer registered only 103°. Except on the first two days of the attack none of the coal-tar fever-

* An eight weeks' chart is rather a formidable document. I hope the analysis of it given below will be considered as doing away with the necessity of reproducing it in the Journal.—S. J. M.
The Sedative Action of Methylene Blue in Psychoses.

—Bodoni (Clinica medica italiana, No. 4, April; Riforma medica, June 24th) concludes that methylene blue, from its power of calming cerebral excitement, diminishing maniacal agitation, and inducing a quiescent state, deserves a place in the therapeutics of various psychoses.

A Powder for Condylomata.—The Riforma medica for April 8th gives the following formula:

R Calomel ........................................... 30 parts; Boric acid ........................................... 15 " Salicylic acid ........................................... 5 "
M. To be applied three times a day.

Chloroform as a Hemostatic.—According to the Journal de médecine de Paris for July 2d, Dr. Spaak, of Brussels, has obtained excellent results from a mixture of two parts of chloroform with one hundred parts of water. This mixture is said to rapidly arrest hemorrhage after tooth extraction.

Ointment for Hemorrhoids.—Nehigan (Der Frauenartz, February 20th; Therapeutische Gazette, July 15th) prescribes the following ointment for hemorrhoids:

R Compound tincture of camphor 1 drachm; Camphor ........................................... 1 " Belladonna ointment 15 drachms.
M. To be applied directly to the painful part.

Iodoform Pencils.—The Journal de médecine de Paris for July 2d attributes the following prescription to Poinot:

R Powdered iodoform, Gelatin, These pencils are soft. Harder ones are made as follows:
R Iodoform, Cacao butter.

Massage of the Abdomen in Deficient Lacteal Secreton.—Schein (Journal de médecine de Paris, July 16th) lauds massage of the abdomen to increase a deficient lacteal secretion. It should be practised daily for half an hour or an hour, the movements being made upward from the pelvis to the breasts. With this may be associated massage of the breasts themselves. Schein’s explanation is that the function of the mammary glands is intimately connected with the amount of blood brought to these glands from the genital organs by means of the vessels of the abdominal walls.

For Lupus Erythematosus.—The Progrès médical for June 17th attributes the following application to Brocq:

R Salicylic acid ........................................... 15 grains; Pyrogallic acid ........................................... 45 " Flexile colloid ........................................... 600 "
M.

For Aortic Insufficiency in Acute Articular Rheumatism.—The Riforma medica for May 29th gives the following as Garrien’s formula:

R Sparteine sulphate ...................................... 1\(\frac{1}{4}\) grain; Syrup of digitalis. Syrup of bitter-orange of each, 450 grains; peel. Gum water ........................................... 900 "
M. S.: A tablespoonful every four hours.

Atropine in Serous Diarrhoea of Nurslings.—The Riforma medica for June 25th gives the following:

R Sulphate of atropine ................................\(\frac{1}{5}\) of a grain; Distilled water ........................................... 450 grains.
M.

From one to three drops may be given, but the general condition must be closely watched, and three drops must not be exceeded.
THE CHOICE BETWEEN THE CÆSAREAN OPERATION AND ACCOUCHEMENT FORCÉ AFTER THE MOTHER’S DEATH.

It is just possible that the advances that have been made in recent years in the technics of the Cæsarean operation, whereby it has almost been robbed of its fatality, have led to such a degree of readiness to resort to it in the case of the living women, and a consequent utter lack of hesitation, to perform it on the dead, as may prove disastrous under certain circumstances, unless special precautions are taken. The danger was lately set forth somewhat graphically by Dr. Colle, at a meeting of the Société centrale de médecine du Nord (Echo médical du Nord, June 25th). Within a week of her expected confinement, a woman fell dead, in his presence, with symptoms of pulmonary embolism. He went home hastily to obtain the instruments necessary for the Cæsarean operation. It was fifteen or sixteen minutes before he got back to the dead woman. Then he rapidly incised the abdominal wall and that of the uterus, tore open the feetal envelopes, and was fortunate enough to extract a child which, although cyanotic, soon began to breathe and was saved.

But an ugly rumor began its rounds; it was whispered that the doctor had killed the mother. This set M. Colle to thinking, and his reflections were not pleasant. He asked himself what material proof he should be able to offer that the woman had actually been dead at the time of the operation, in case he was accused; and prosecutions of physicians were so easily set on foot! At the meeting he mentioned these reflections and cited instances of women supposed to be dead who had regained consciousness during the Cæsarean operation. He was inclined, therefore, to prefer accouchement forcé in cases of the supposed death of the mother, for it could be performed at once, and the woman, if not really dead, be saved as well as the child, while the accoucheur’s reputation was safe also.

M. Oui agreed with M. Colle that, after the mother’s death, accouchement forcé was to be preferred to the Cæsarean operation, at least in private practice, for in the cutting operation the same precautions should be observed as if the mother were living, and that might really be the case. He cited Tarnier as having called attention to the very important consideration that it was always necessary to lose more or less time in obtaining the consent of the family to the performance of hysterotomy, whereas one could proceed at once to extraction per vias naturales and incur no reproach. M. Oui would use the forceps if he happened to have the instrument with him; otherwise there was but one resource, podalic version.

Perhaps the obstetrician of the present day may fairly be expected to go to a case of confinement prepared to perform the Cæsarean operation at short notice and with all the attention to detail that it requires, but certainly it can not be required of him that he should be thus ready in the case of a woman who, being in apparent health, falls dead in his presence while he is making an ordinary professional call on another member of the household, and is then ascertained to have been pregnant with a viable child—and this was M. Colle’s experience. But the physician always has his hands with him, and can proceed instantly to dilate the cervix, rupture the membranes, turn by the feet, and extract—and that, too, without asking anybody’s permission.

THE INGUINAL CANAL AS AN APPROACH TO THE ABDOMINAL CAVITY IN GYNECOLOGICAL OPERATIONS.

It has long been our conviction that most if not all of the various ingenious operations devised of late years to secure fixity of the uterus or to tether it according to the operator’s estimate of what amount of mobility it was desirable to allow it—the multifarious forms of “fixation” and “suspension”—were not founded on sound principles. This view was ably upheld by Dr. Albert Goldspohn, of Chicago, in a paper presented before the Section in Obstetrics and Diseases of Women at the Columbus meeting of the American Medical Association and published in the association’s Journal for July 22d. Dr. Goldspohn shows conclusively, it seems to us, that, in so far as these procedures are efficient, they are very prone to lead to serious complications in the event of subsequent parturition or invite intestinal strangulation, and that, in so far as they do not tend to bring about such troubles, they are rendered ineffectual by the evolution of the uterus in case pregnancy occurs. He would therefore limit all such operations to women who either are barren to begin with or can justifiably be made so at the time of the operation. Practically, he would restrict them to instances of decided prolapse giving rise to serious suffering.

There is one procedure, however, which Dr. Gold-
spohn thinks free from objection, that of shortening the round ligaments for retroversion, but it is an operation far more extensive than Alexander's. It resembles the Bassini operation for hernia and is called by the author the "improved and extended Alexander operation." He states that he first performed it in September, 1893, when he removed a diseased Fallopian tube and ovary through the internal inguinal ring. It was not until 1898 that he published a description of it, in the American Gynecological and Obstetrical Journal for February of that year. In an Alexander operation he now always dilates the internal abdominal ring, if only for exploratory purposes. He is thus enabled to free the annexa if there are adhesions, remove the Fallopian tube with or without the ovary, raise and suspend a prolapsed ovary, or effect salpingostomy. In one instance he has removed a tubal-gestation sac, which was on the point of rupturing, leaving the ovary, the only one the woman had. He always closes the wound in the same way as after a Bassini operation for hernia, and thereby, he says, "We not only avoid the supervision of hernia, but incidentally cure a number of inguinal herniae that are impeding or are fully developed." From January 1, 1897, to May 29, 1899, he performed the operation sixty-five times, and without a death. Theoretical considerations seem to us to favor Dr. Goldspohn's method in cases in which a large opening into the abdomen is not required, and it appears not unreasonable to expect that his good results will be followed by many others, in his own practice and that of surgeons in general who have conservative tendencies.

THE RECRUDESCENCE OF SYphilis DUE To INFLUENZA.

The sequelae of influenza are certainly protean. To one of them, the active recrudescence of latent or quiescent syphilis, Mr. J. Warrington Haward, F. R. C. S. Eng., surgeon to St. George's Hospital, London, particularly directs attention in the Lancet for July 1st. Influenza, he thinks, is comparable to malarial fever in its power to bring out some of the later manifestations of syphilis and to make manifest any latent syphilitic taint. He mentions the case of a woman, forty-two years old, who had been infected by her husband eighteen years before. She was intelligent and aware of the nature of her disease, and gave a very clear history of her symptoms. She had had a chance on the vulva, followed by well-marked secondary symptoms which had lasted for a year and a half. For the following year she had remained free from symptoms, having been continually under treatment, but during the succeeding year she had again suffered from ulceration of the throat and skin, for which she had been treated. Then, so far as she could remember, she had remained well until the time of a recent attack of influenza, but in that attack rubial bulbe appeared over the body and developed into numerous and extensive ulcers. At the same time her hair fell out so that she became almost bald, and from an anemic pallor her complexion became of a dull bistre tint. Then ulceration of the soft palate occurred, leading to an extensive perforation. A large peristelial node formed over the back of the radius, and subsequently she had ulcers between the toes.

The recurrence in this case, says Mr. Haward, was of unusual severity, but he adds that in other cases which he has observed there has seemed to be a special tendency to ulceration. This tendency and the proneness to breaking down and necrosis of inflammatory products, he remarks, are indications of lowered vitality, and they should be borne in mind as guides in the treatment. In such cases, he thinks, the calomel vapor bath will be found very efficacious. The recent occurrence of influenza he considers to be no bar to the administration of mercury, and in the cases he has observed he has found mercurial treatment to be always of the greatest benefit. He is convinced that, however remote the original syphilitic affection may have been, in nearly every case of syphilis in which fresh symptoms are evoked, benefit will result from the administration of mercury, and he thinks he has witnessed good results from the simultaneous employment of a fresh decoction of sarsaparilla.

SOME SURGICAL SEQUELae OF INFLUENZA.

We seem to be constantly encountering new horrors to which the nosological monstrousness known as influenza may give rise. At the recent meeting of the German Society of Surgery (Centralblatt für Chirurgie, July 8th) Dr. F. Franke, of Brunswick, after mentioning several nervous affections which were apt to be mistaken for diseases susceptible of cure by operative procedures, to the discomfiture of everybody concerned, stated that he had seen six cases of perforating ulcer of the nose, four of which had come on during the course of influenza or immediately after it, and two in persons who had previously had the disease. He referred to purulent otitis and pleural empyema as being too well known to call for more than mention. The bone diseases, he thought, were usually benign, seldom terminating in suppuration and necrosis, the inflammation being ordinarily plastic. In two instances he had observed a nodose periostitis of the skull somewhat suggestive of gouty thickening of the ends of the phalanges and also of spinæ ventosa of the smaller long bones. The joint affections observed by him, he said, had invariably been of bony origin. The pains in the sole of the foot or in the heel so often complained of by influ-
enza patients he attributed partly to inflammation of the plantar fascia, partly to plantar neuritis, and partly to periostitis of the calcaneum. The “swollen foot” (Fussgeschwulst), also of frequent occurrence, depended on osteitis of the tarsus or metatarsus. In a few cases he had seen non-purulent myositis, bursitis, and inflammation of the sheaths of tendons. His experience had been that rest was the great element in the treatment of these cases; for the plantar pains he recommended a soft-rubber sole stitched (not otherwise fastened) to the bottom of the shoe.

Sudden blanching of the hair.

The subject of sudden changes in the hair occurring soon after a violent emotion, and apparently in consequence of it, is perhaps all the more interesting from the paucity of well-authenticated cases. An instance reported by Dr. F. Boissier in the Progrés médical for June 17th seems particularly noteworthy in some of its features. A healthy and vigorous peasant witnessed the horrible sight of his own child being apparently trampled to death by a mule. It turned out that the little fellow was only bruised, but of this the father was not aware, and he hastened away for assistance. While he was yet running he experienced, besides his terrible fright and anguish, a trembling sensation, palpitations, and a feeling of cold and tension in the face and on the head. The next day the hair of his head, his beard, and his eyebrows were shed in great masses; at the end of a week he was absolutely devoid of hair. Moreover, he had been of a very dark complexion and much sunburned, but his face became much paler. The hair began to grow again at once, at first in the form of a colorless down, but soon with the ordinary qualities of hair, save that it was more silky than the original hair and perfectly white. The hairy parts below the neck were not affected.

Napoleon’s idea of the itch.

Possibly the great Napoleon was a believer in the psoriatic origin of disease. The Journal de médecine de Paris for July 9th quotes the following from the Gazette médicale de Paris as having been attributed to him by General Gourgaud: “The itch is a terrible disease. I caught it at the siege of Toulon. Two canoneros who had it were killed in front of me, and their blood covered me. It was badly treated, and I still had it in Italy and with the army in Egypt. On my return, Corvisart relieved me of it by applying three blisters to my chest, which brought about a salutary crisis. Before that I was lean and hungry-looking, but since then I have always been in good flesh.”

Malarial aortitis.

M. Lancereaux appears to have discovered a new disease of the aorta. At a recent meeting of the Paris Academy of Medicine (Indépendance médicale, July 5th) he reported that he called it malarial, not only because it was met with almost exclusively in persons who had had attacks of intermittent fever and lived in malarious countries, but also because of its special features. It was encountered in subjects between thirty and sixty years old. It had its seat in the ascending portion of the arch of the aorta. It began in the outer coat, which became congested and thickened, and from that it spread to the middle coat and finally to the intima, which became thickened and affected with elevated patches. Among the consequences of these lesions he had observed inflammation of the adventitia, which might extend to the nerves of the cardiac plexus and occasion angina pectoris, also destruction of the middle coat leading to the formation of sacciform aneurysms. He described the course of malarial aortitis as very slow, and said that it did not begin until several years after the infection. It was necessary to distinguish it from arteriosclerosis and from syphilitic arteritis. The prognosis was grave, and the affection often terminated in sudden death. The preventive treatment consisted in a strengthening regimen and hydrotherapeutics; the curative, in the use of potassium iodide and milk. The angina pectoris was to be treated with calmotives, and aneurysm with subcutaneous injections of gelatin.

The dilatation treatment of phimosis.

Brisk dilatation, or, rather, dilaceration, of the terminal part of the prepuce has been practised to a considerable extent by some surgeons. Dr. Schilling, of Nuremberg (Münchener medizinische Wochenschrift, 1899, No. 11; Wiener klinische Wochenschrift, July 13th), reports a number of cases occurring in children in which gradual dilatation with sounds resulted in a permanent cure. In some of them the preputial orifice was originally very small.

Pseudo-influenza.

No doubt the diagnosis of influenza is often made on insufficient grounds. Professor von Jakobs, of Prague (Berliner klinische Wochenschrift, 1899, No. 20; Wiener klinische Wochenschrift, July 13th), reports a number of cases of streptococcus pneumonia and diplococcus pneumonia in which the mistake was made. In his opinion, a case should not be said to be one of influenza until the typical bacillus has been found.

Steam as a hemostatic application to the liver.

The therapeutic efficiency of simple measures has been illustrated anew in certain experiments performed by Dr. Fiore and Dr. Gianaola, an account of which is published in a supplement to the Polliclinico and summarized in the Deitsche Medicinal-Zeitung for July 13th. They cut portions of the liver from eight dogs, in one instance as much as a whole lobe, and then applied to the bleeding surface a stream of steam, holding the nozzle of the apparatus about three inches away, so that the temperature of the steam as it impinged upon the liver was 158° F. Superficial coagulation took place in a few seconds. The usefulness of such a procedure in cases of wound of the liver in the human subject can hardly be doubted.

The study of botany in the vacation schools.

Science for July 7th publishes a statement by Miss Sanial, on behalf of the committee on nature study of the Torrey Botanical Club, to the effect that wild flowers are needed by the children in the vacation schools of New York. Persons living in the country around New
York will doubtless be glad to contribute such material. By writing to the board of education, labeling the communications "for vacation schools," they will obtain the necessary blanks.

THE CALIFORNIA LUNATIC ASYLUMS.

It is painful to learn of the serious charges against the management of the Agnesses asylum, now under investigation by the board of managers of the institution, sitting jointly with the State lunacy commission. Not all that some of the newspapers have said seems borne out by the testimony thus far taken, but we can hardly avoid the conclusion that the asylum has been woefully mismanaged. A scandal concerning the Napa asylum is next to be investigated.

ITEMS.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, cholera, and plague were reported to the surgeon-general during the week ending July 29, 1899:

| Changes of Address.—Dr. J. N. F. Elliot, to No. 421 South Warren Street, Syracuse, New York; Dr. Michael Lucid, to No. 401 Montgomery Street, Syracuse, New York. |  |

Army Intelligence.—Official List of Changes in the Stationary and Duty of Officers serving in the Medical Department, United States Army, from July 22 to July 29, 1899:

ASHFORD, Bailey K., First Lieutenant and Assistant Surgeon, United States Army, is detailed as an additional member of the board of officers convened by Par. 3, S. O. 135, c. s., with WELLS, George M., Captain and Assistant Surgeon, United States Army, relieved.

BAILEY, Guy G., Acting Assistant Surgeon, United States Army, will proceed from Mackinac Island, Michigan, to San Francisco for temporary duty.

CRAIG, Charles F., Acting Assistant Surgeon, United States Army, will proceed to Havana for duty at Camp Columbia, Cuba.

DEVERUX, John R., Acting Assistant Surgeon, United States Army, will proceed from Fort Hamilton, New York, to Camp Meade, Middletown, Pennsylvania, for duty at the camp hospital.

DISNEY, F. A. E., Acting Assistant Surgeon, United States Army, will proceed to Camp Meade, Middletown, to accompany the Nineteenth Infantry to Manila.

DUVAL, Douglas F., First Lieutenant and Assistant Surgeon, United States Army, is granted leave of absence for one month.

EWING, Charles B., Captain and Assistant Surgeon, United States Army, is relieved from further duty at Fort Brady, Michigan, and will proceed to San Francisco for duty with the Third United States Cavalry upon its arrival.

HEIZMANN, Charles L., Major and Surgeon, United States Army, is assigned to duty as chief surgeon, Department of Texas.

KNEEDLER, William L., Major and Brigade Surgeon, United States Volunteers, is relieved from further duty in this division, and will comply with the instructions contained in Par. 40, S. O. 129, c. s., H. Q. A.

MAUS, Louis M., Major and Surgeon, United States Army, is detailed temporarily as a member of the army retiring board ordered to meet at Governor's Island, New York, by Par. 1, S. O. 150, during the absence of HOWARD, Deane C., Captain, and Assistant Surgeon, United States Army.

Mcculloch, T. A., Acting Assistant Surgeon, United States Army, will report to CRESS, George O., Captain, Fourth Cavalry on the transport Tacoma, for duty on that ship during the voyage to Manila, and return to San Francisco.

WOODRUFF, Charles E., Captain and Assistant Surgeon, United States Army, will proceed by the first available transport to Manila.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Week ending July 29, 1899:

ATLEE, L. W., Surgeon. Detached from the Bennington and ordered home via Solace.

JOHNSON, M. K., Passed Assistant Surgeon. Detached from the Naval Hospital, New York, and ordered to the Marietta.

LIPITT, T. M., Assistant Surgeon. Detached from the Solace and ordered to the Baltimore.
ITEMS.—MARRIAGES AND DEATHS.—SPECIAL ARTICLES.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending July 27, 1899:

Mead, F. W., Surgeon. To proceed to New York and assume temporary charge of the Purveying Depot.

Geddings, H. D., Passed Assistant Surgeon. Relieved temporarily from duty on the commission for the scientific investigation of yellow fever and assigned to temporary duty in the Hygienic Laboratory. To proceed to Boston for special temporary duty.

Ferry, J. C., Passed Assistant Surgeon. Detailed for duty in the office of the United States Consul at Hongkong, China.

Gardner, C. H., Passed Assistant Surgeon. To assume temporary charge of the Port Townsend Quarantine.

Sprague, E. K., Passed Assistant Surgeon. Granted leave of absence for twenty-seven days from August 7, 1899.

Wickes, H. W., Passed Assistant Surgeon. Granted leave of absence for thirty days from August 6, 1899.

Tabb, S. R., Assistant Surgeon. Upon being relieved from duty at Baltimore, to proceed to Savannah and assume command of the service.

Foster, M. H., Assistant Surgeon. Upon being relieved from duty at Savannah, to proceed to the Port Townsend Quarantine Station and report to the commanding officer for duty.

Luysden, L. L., Assistant Surgeon. To proceed to Port Townsend, Washington, and assume temporary charge of the service.

Billings, W. C., Assistant Surgeon. Relieved from duty at the Immigration Depot and directed to report to the commanding officer at New York for duty and assignment to quarters.

Fox, Carroll, Assistant Surgeon. To report to the commanding officer at Baltimore for duty and assignment to quarters.

McClellintic, T. B., Assistant Surgeon. To report to the commanding officer, Cape Charles Quarantine, for duty and assignment to quarters.

Currie, D. H., Assistant Surgeon. To report to the commanding officer at Louisville for duty and assignment to quarters.

Goldberger, Joseph, Assistant Surgeon. To report to Surgeon L. L. Williams, Immigration Depot, New York, for duty.

Korn, William A., Assistant Surgeon. To report to the commanding officer, Chicago, for duty and assignment to quarters.

Holt, J. M., Assistant Surgeon. To report to the commanding officer, St. Louis, for duty and assignment to quarters.

Trotter, F. E., Assistant Surgeon. To report to Surgeon L. L. Williams, Immigration Depot, New York, for duty.

Vogel, C. W., Assistant Surgeon. To report to the commanding officer, Boston, for temporary duty and assignment to quarters.

Tuttle, Jay, Acting Assistant Surgeon. Granted leave of absence for seven days.

Promotions.

Gain, Henry, Hospital Steward. To be hospital steward and chemist.

Stearns, W. L., Hospital Steward. To be hospital steward and assistant chemist.

Married.

Austin—Bush.—In Terry, Mississippi, on Wednesday, July 26th, Dr. W. G. Austin, of Utica, Mississippi, and Miss Ada Bush.

McLaughlin—Greene.—In Westfield, Massachusetts, on Wednesday, July 26th, Dr. James S. McLaughlin and Miss Mary E. Greene.

Died.

Badger.—In Boston, on Monday, July 24th, Dr. George A. Badger, in the seventieth year of his age.

Charbonnet.—In New Orleans, on Sunday, July 23rd, Dr. J. Numa Charbonnet, in the thirty-fourth year of his age.

Lomax.—In Troy, New York, on Saturday, July 22nd, Dr. Joseph D. Lomax, in the seventy-second year of his age.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By ARTHUR N. TAYLOR, LL. B.

CIVIL MALPRACTICE, INCLUDING GENERAL LIABILITY OF PHYSICIAN TO PATIENT.

(Continued from page 172.)

Right to Leave Practice Temporarily.—The preceding question brings us to the consideration of when and
under what circumstances the physician may with legal safety go away and leave his practice. The law books show very few cases throwing light upon this question, which probably argues that physicians exercise great care in determining when they may safely leave their practice, and also in selecting competent substitutes to whose care the health and lives of their patients are to be temporarily intrusted.

As a general rule it can be laid down that a physician should never go away and leave his practice without arranging for some competent physician to attend his patients, but under what circumstances and conditions he is justified in leaving his patients in the care of such a physician is not quite so clear.

It is easy to see upon principle that a physician, possessing adequate skill and knowledge to enable him to understand the condition of his patients, who, by the careful exercise of his good judgment, determines with a reasonable degree of certainty that they are beyond the point of danger, may safely leave them under the care of a competent substitute; but whether the law will require so high a test of care is doubted. We have but just quoted an instruction from Justice Pryor, in which he said: "The defendant swears that at his last visit he noticed the plaintiff that he was going out of town, and indicated to her a physician who would attend her in his stead. If this statement be true, the defendant's absence is excused, and you must exonerate him from this imputation of neglect." While in this case the patient was without doubt in grave need of medical attendance, yet there is no evidence shown in the report that her life was in imminent danger or that she was even in a critical condition. And, again, in the case of Dashiel vs. Griffith, Justice Roberts says: "If the defendant had in his treatment of the finger, prior to the 24th of February, exercised reasonable care, skill, and diligence, and then, because of the illness of his father, had turned the plaintiff over to Dr. — , a competent physician, for the further treatment of her finger, and the plaintiff refused to go to Dr. — for treatment, then the liability of the defendant ceased." But here again the plaintiff was merely suffering from a felon, and when the defendant last saw the patient it was thought that the diseased member was doing as well as might be expected. In the case of Ewing vs. Goode, decided in the United States circuit court, the defendant had operated upon the plaintiff for a cataract.

The operation took place on the 25th of September; it was characterized a smooth and successful operation, and the wound was quite healed in about ten days. About the 19th of November following the plaintiff complained of pain in the eye; the defendant carefully explored the eye with the ophthalmoscope, but could discover no cause for the pain. The pain continued, and repeated examinations were made at short intervals apart, but, as no cause for the pain could be found in the eye, it was diagnosed as neuraglia of the fifth nerve and treated as such. On the 9th of December the defendant thought he saw a slight increase in the tension of the eye, but was doubtful about it. This was a symptom indicating glaucoma, and one for which the eye had been carefully examined at short intervals since the pain commenced; the defendant accordingly prescribed eserine. On the 10th of December the defendant examined the eye again and found no increased tension and no other evidence of a glaucomatous condition, though the pains continued. On the 11th of December he confirmed his conclusion that there was no increased tension by making another examination. After this he remained in the city until the 18th of December, and receiving no calls from the plaintiff went away, leaving his practice in the hands of a competent physician, who understood the plaintiff's case and had assisted in the operation on the eye and had examined it after the pain commenced. On January 6th the defendant returned and found an increased tension amounting to +1 and distinct symptoms of glaucoma. An operation was promptly performed with the hope of relieving the pain and retaining the eyeball. This operation proving unsuccessful in accomplishing the desired effect, the eyeball was finally extracted. The court gave special attention to the right of the defendant to leave his practice on the 18th of December as he did. After carefully reviewing all of the above facts, Judge Taft said: "As to the right of (the defendant) to leave the city on the 18th of December, when his patient had not called him for a week, and while he was presumably following the precautionary and alleviating prescriptions of eserine and phenacetine, I do not think there can be any doubt, if he made provisions for the attendance of a competent oculist in case of a call?"

All of the cases cited above are those in which the physician's right to temporarily leave his practice is upheld, and a careful examination of the reports has failed to discover a precedent in which the right of the physician to leave his practice in the hands of another competent physician is denied; yet it seems that the right to leave one's practice should depend upon the same principles which ordinarily are applied as a test of liability—viz., if the physician, by the careful exercise of ordinary skill and knowledge, believes that he may safely leave his patients to the care of another, he will be justified in so doing; if, on the other hand, a patient's condition is such that a physician in his best judgment thinks a change of physicians would be injurious, nothing short of dire necessity should induce him to permit the substitution.

Liability of Physician for Negligence of One whom he Recommends.—Having determined that the physician has under ordinary circumstances the right to leave his practice in the hands of a competent substitute, it becomes pertinent to consider what, if any, responsibility such physician bears for the acts of his substitute. Should the physician recommended be in a legal capacity to act, as by the agent of the physician recommending him,—that is, if he is employed by him as an agent, then the law applies the legal maxim qui facit per alium facit per se, and holds the recommending physician liable for all negligent or improper professional conduct of his agent. But if, on the other hand, the physician recommended is in independent practice, and is properly esteemed a man of ordinary professional ability and of proper discretion, the physician recommending him will not be held responsible for any error he may commit.

When a regular railroad physician, upon going away for a short time, gave instructions that if anything happened the railroad company should call upon a certain other doctor, and an accident did occur and the desig-
nated physician was called in and improperly treated the case, it was held that the regular physician was not liable for such improper treatment, there being no evidence to show that the physician recommended was in the employ of the defendant.*

In the case of Meyers vs. Holborn,† a physician promised to attend a patient during confinement. A short time before the event took place he left the city for a three days' vacation, but first visited the patient and made an examination of her condition, from which he concluded that his services would not be required for several days. During his absence, however, the child was born, and according to arrangements made by the defendant, before leaving, the patient was attended by another physician, who severed the umbilical cord so near the child's body that it was impossible to tie it, in consequence of which the child died. An action was brought by the husband against the physician employed to attend the case for this negligence of his substitute, but the liability was denied by the court, which, speaking through Justice Gummere, said: "Dr. — (the physician recommended to attend the patient) and the defendant were each of them practising physicians within the State, having no business connections with one another, except that Dr. — was attending the patients of the latter while he was temporarily absent. Even if it be admitted, therefore, that Dr. — was employed by the defendant to attend upon the wife of the plaintiff, that fact did not render the defendant liable for his neglect or want of skill in the performance of his service, for an examination of the authorities will show that a party employing a person who follows a distinct and independent occupation of his own is not responsible for the negligent or improper act of the other."

It will be observed from the foregoing opinion that in New Jersey the courts go so far as to hold that a physician can not be held for the negligence of another physician whom he employs to perform certain professional services, if such other physician has a distinct and independent practice. While there is no question about the correctness of the principle of law by which the court arrived at this conclusion, it is doubted whether the courts of other States will find the principle applicable to this particular condition; therefore, a physician can not be safely advised to employ another physician to attend to his practice, even though such other physician does enjoy an independent practice, if he desires to escape liability for the professional errors of such other physician.

A question which might be suggested by those preceding is one which arose in the case of Jones vs. Vroom.‡ In this case the defendant, a physician in general practice, who was attending the plaintiff for typhoid fever, was informed by her that she had a pain in one of her eyes and that the sight was beginning to leave it, and was asked to send her an oculist. The defendant laughed at her, and told her there was nothing the matter with the eye, but upon further request promised to send her an oculist. He did not comply with the request, however, and as an excuse for not doing so said he had forgotten the matter. Finally the nurse telephoned for an oculist, who said, upon examining the eye, that he could do nothing for it, but that he might have done something if he had been sent for sooner. The plaintiff sued the defendant for not securing the oculist when requested, but the defendant's liability was denied. The court said: "The defendant was employed to treat her for fever, and his employment imposed no duty on him to provide her with a specialist for her eye." This case was tried simply upon the question indicated in this quotation; it therefore is possible that other questions might have been raised upon which a different decision could be reasonably expected. Any way, it is never safe for one to undertake to do a thing without fulfilling the agreement, whether there is a consideration or not, and a physician can not safely ignore complaints regarding conditions which by any probability relate to the condition for which he is treating the patient.

*(To be continued.)*

**Pith of Current Literature.**

The Serum Treatment of Typhoid.—A London correspondent of the Interstate Medical Journal for July writes that the main point of interest centres round the serum-treatment experiments which are being conducted in different parts of the world. One of the latest commissioners, Professor A. E. Wright, of the Army Medical School, Netley, took advantage of his visit to the typhoid districts of India to avail himself of the opportunity of inoculating certain British troops against this dread enemy of the soldier on foreign service. It appears that in the "West Riding" regiment, stationed at Bangalore, two hundred and fifty of the soldiers volunteered to be inoculated with the typhoid serum as a protectionary or prophylactic measure. When at Rawal Pindi, Dr. Wright addressed the "Queen's" regiment on the advantages of inoculation, mentioning that fifteen hundred soldiers are annually ill with enteric fever, and that one out of every five dies. Out of two hundred attendants at the Maidstone Asylum in Kent in the south of England, ninety-five persons were inoculated and none contracted fever, while of those who refused to undergo the process, nineteen suffered from the disease. Dr. Kharalimen, of eight young subalterns, six consented to inoculations, and the other two agreed to take their chance; of these latter, one was very ill with typhoid, the other died; the inoculated officers escaped. Professor Wright also inoculated the troops in garrison at Lucknow, three hundred of the third Hussars and one hundred and twenty Camerons. Diligent experiments are being made with the typhoid serum in more than one physiological laboratory in this country.

The Pathogenesis of Strabismus.—Dr. Alexander Duane (Archives of Ophthalmology, May) concludes an interesting paper as follows: Exophoria and divergent squint may be due to: 1. Underaction of an adductor (insufficiency in the true sense of the word) or over-action of an abductor, due to abnormalities in structure, insertion, or innervation (muscular squint or exophoria). Not very frequent by itself, but frequent as a complication. 2. Over-action of the diverging power (divergence excess). Fairly common. 3. Underaction of convergence (convergence insufficiency). Very fre-
quently. May be either accommodative (in myopes) or non-accommodative. 4. One or more of the above anomalies combined (mixed conditions). Such a combination usually obtains in long-standing and marked cases of concomitant divergent squint. Esophoria and convergent squint may be due to: 1. Underaction of an adductor (true insufficiency) or overaction of an adductor, due to abnormalities in structure, insertion, or innervation (muscular squint or esophoria). Not very common by itself, but frequent as a complication. 2. Overaction of convergence (convergence excess). Very frequent. May be either accommodative (in hypermetropes) or non-accommodative. 3. Underaction of the diverging power (divergence insufficiency). Rare. 4. One or more of the above causes combined (mixed conditions). Such a combination usually obtains in long-standing and marked cases of concomitant convergent squint. It is by following an etiological classification like this that we attain, in my belief, the best success in both diagnosis and treatment.

Holocaine versus Cocaine in Ophthalmic Surgery and Diseases.—Dr. Hermann Knapp (Archives of Ophthalmology, May) draws the following comparisons between holocaine and cocaine:

1. Holocaine is as powerful a local anaesthetic as cocaine; over which it has several marked advantages:
   - It acts (one-per-cent. solution) in a shorter time, a third to one minute, which makes its use very valuable, particularly if we want to anasthesize the iris. After a corneal section, either for a glaucoma or cataract operation, we can readily anesthetize the iris by pressing the wound open and letting one or two drops fall into the gap to reach the iris.
   - It does not interfere with the circulation, which accounts for its alleged germicide properties. Blood being the best safeguard against infection, the outflow of blood during the operation carries also the germs away from the wound. It is a very old experience that wounds for the extraction of cataracts that bleed never were seen to suppurate. Cocaine, by its constriction of the blood-vessels and other tissues, sucks tissue juice and germs inward, and thus favors infection. Cocaine, causing anemia, has the advantage over holocaine, first, in the diagnosis of vascular organs—for instance, the swelling of the turbinals of the nasal passages—and secondly, in facilitating the performance of operation. A combination of the two may unite the advantages of both.
   - Holocaine does not dry the cornea so much as cocaine does. Dr. Knapp can not confirm the statement of authors that it does not dry the cornea at all. Holocaine, not interfering with the circulation, possibly dries the cornea only because the anaesthesia gives no incentive to winking. Be this as it may, he has often noticed in cataract extractions that he had to let a drop of liquid fall on the cornea after holocaine anaesthesia as well as after that of cocaine, only not in the same degree.

2. For operative work on the eye, especially on the cornea, I have almost completely substituted holocaine for cocaine. For the removal of foreign bodies holocaine is an ideal anaesthetic. It renders the cornea insensible in half a minute, and does not suck in germs that may have contaminated the foreign body.

3. Cocaine is an anaesthetic but no remedy. In all painful diseases of the outer coats of the eye, it ought to be replaced by holocaine. If in contagious ophthalmia we instil cocaine into the conjunctival sac, we may relieve the pain, but with the tissue juice the germs are sucked deeper; not so in using holocaine. When the surgeon of to-day has cut his finger with a knife passed through tissue of doubtful purity, he no longer burns that wound out, but makes it bleed. Holocaine can be combined with topical remedies, but Dr. Knapp would not countenance the popular combination of cocaine with astringents.

4. As to holocaine being a strong germicide and an excellent remedy for septic ulcers of the cornea, as advanced by Haskett Derby, the author can say that he has seen good results from the combined use of holocaine with antiseptics and caustics; holocaine alone also has had a good influence, but in his practice not in so large a proportion as Derby states.

Dr. Knapp concludes by saying that in holocaine we have not only an excellent local anaesthetic, but also a valuable therapeutic adjuvant in combination with other remedies.

An Absorbable Intestinal Coupler.—At a meeting of the Chicago Medical Society, held on May 24th, Dr. Jacob Frank (Chicago Medical Recorder, July) read a paper on an absorbable intestinal coupler invented by him and designed to replace the Murphy button.

The apparatus consists of two decalcified bone collars with four needle-hole perforations at the apex or shoulder of each collar, and one piece of ordinary pure gum-rubber tubing, of the kind used for drainage, large enough to just fit inside of the coupler. It is prepared for use in the following manner: A collar is slipped over a piece of rubber hose until the apex is brought to a level with the end of the tubing, when an ordinary medium-sized curved needle, threaded with silk, is carried through each opening and tied; this, as can readily be seen, fastens the collar to the tube; the other collar is next fitted snugly to the one already fastened, and is then in like manner sewed to the other end of the tube and placed in absolute alcohol until they are to be used. The rubber tubing to which the collars have been sewed, being hollow, serves subsequently for the passage of the intestinal contents after being placed in situ. The couplers are made in eight different sizes, the rubber hose corresponding to the size of the coupler.

The bases of the collars, which are formed into a broadened rim, are held firmly in apposition throughout their entire circumference, after being sewed to the rubber. The intestinal ends are brought over each collar and crowded within the line of junction of the two; of necessity the latter are forced apart, and the rubber tube is put upon the stretch, thus affording pressure of adequate amount to cause a necrosis of the interposed intestines. The collars dissolve in due course of time and but a small piece of rubber tubing is left in the intestinal canal to pass off with the feces. Even if retained, the rubber will become macerated, as it is composed of vegetable substances.

The collars are carved from long compact bones which are obtained from oxen. They are then subjected to the decalcifying fluid, which consists of a ten-per-cent. solution of absolute hydrochloric acid, and are removed from this fluid in six hours and placed under a stream of cold water for half an hour to remove the salts which have formed. They are then placed in a fresh decalcifying fluid of the same strength, or less as required, and the process is repeated until they are completely deprived of their calcarous constituents,
when they are washed with cold running water, so that all traces of acids and phosphates are removed and the collars have acquired an almost transparent appearance. Then they are practically dehydrated by treatment with pure cologne spirits, and finally immersed in absolute alcohol, which renders them sufficiently tenacious for their purpose. In order to insure against shrinkage, they are not sewed together for use until they have been kept in absolute alcohol for from one to two weeks.

The coupler is used in the following manner: Murphy’s puckering string is placed about each severed end of the intestine. The operator slips an intestinal end over one of the collars, to the line of junction, at the same time gently spreading the collars apart to facilitate the easy access of the gut. An assistant takes charge of the ends of the puckering string, and when the gut has been brought over the collar he makes one knot, and draws down until his puckering ligature strikes the rubber tubing, which he will perceive by the resistance offered; the tube will not permit too tight drawing of the puckering ligature on account of its resiliency. The second knot is tied and cut short. The other intestinal end is then slipped over the other collar and tied in the same manner. The ligature is cut off short and the clamps are immediately removed. When the operated portion of the bowel will be slowly distended with gas. An interrupted Lembert suture should be taken around the border, with an intestinal needle threaded with No. 2 silk, to make the work more secure. The rent in the mesentery should be sewed.

For gastro-enterostomy, or side-to-side anastomosis, Murphy’s method can be used—that is, placing the puckering string before opening the viscous, but the author prefers to make the opening into the intestine or stomach first and then take the suture by the over-and-over method. In opening the intestine longitudinally or transversely, it is very common for the mucous membrane to roll out. Should this be the case, he advises the removal of the everted mucosa with either the scissors or currette, before taking the suture, as it will insure a much more satisfactory, cleaner, and safer operation.

In the discussion which followed, Dr. Carl Beck reported having used Frank’s coupler with success. Dr. J. B. Murphy, while combating the idea that any other than exceptional danger attached to the use of his button, said, with reference to Dr. Frank’s coupler, if it could be so decalcified that he could regulate the length of time it would last before being dissolved, it was, in his opinion, theoretically the best device that had so far been brought forward for intestinal anastomosis, and he congratulated Dr. Frank. The line of union produced by pressure approximation was certainly the most satisfactory.

Menstruation by the Ear.—M. Lermoyez (Presse médicale, July 15th) recently reported to the Société médicale des hôpitaux the case of a young girl in whom menstruation had been established three years previously, the flow taking place from the right ear. Usually every month, after a period of prodromes consisting of headache and general lassitude, a flow of clear non-coagulable blood took place from the right ear, in which no preexisting local lesion could be determined. After three years the ordinary genital discharge began to take place, gradually replacing that from the ear, which only occurred every two or three months. The author remarks that the nature of the auricular hemor- rhage admitted of no doubt, being periodical, preceded by a regular local molimen, and the blood being non-coagulable. As to the ear, the blood came from the walls, the tympanum being intact. Hysteria would naturally be thought of, yet the patient showed none of the ordinary stigmata of that disease. The author, nevertheless, considered this auricular menstruation as in all probability of that nature, for on the side of the bleeding ear there was slight hyperesthesia of the tympanum and auditory canal, as well as a certain degree of auditory anesthesia; and the coincidence of these symptoms is, according to the author, one of the best signs of auricular hysteria that we have.

Appendicular Inflammation as a Cause of Inflammatory Disease of the Right Ovary and Tube.—Dr. A. J. Ochsner (Journal of the American Medical Association, July 23rd) thus sums up a paper presented to the meeting of the American Medical Association: “Judging from this year’s experience, as well as from my very much larger former observations, I am certain that the matter of secondary infection, especially of the right ovary and tube, has been very much under-estimated. The following conclusions seem to be borne out by this experience: 1. Appendicitis frequently causes inflammatory diseases of the right ovary and tube, and occasionally the left side is also involved. 2. This condition is especially likely to give rise to chronic invalidism, because of the periodic exacerbation resulting from the congestion due to menstruation. 3. In operating for the relief of pyosalpinx, the condition of the appendix should always be determined. 4. In operating for chronic or recurrent appendicitis in patients suffering also from dysmenorrhoea, the right ovary and tube should be examined. 5. If the pain is limited to the right side in severe dysmenorrhoea, the appendix is frequently primarily involved. 6. In catarrhal appendicitis in which there is a fecal obstruction in the appendix, or in appendicitis obliterans, the pain is frequently most severe during menstruation. 7. In patients who have recovered from gangrenous appendicitis there is frequently no further disturbance from the condition of the appendix, except the digestive disturbance due to adhesions, while the secondary disturbance in the ovary and Fallopian tube may continue to be very great. 8. In young girls suffering from dysmenorrhoea the history should be followed very carefully, in order to determine the presence of a previous attack of appendicitis. 9. The fact that many of these cases are mistaken for salpingitis accounts for the theory that appendicitis is more common in men than in women.”

Purulent Ophthalmia treated by Potassium Perman- ganate.—M. Vian (Gazette hebdomadaire de médecine et de chirurgie, June 13th) recently presented to the French Society of Ophthalmology a case of purulent ophthalmia in the adult, cured by a ten-per-cent. solution of permanganate of potassium. The solution was applied twice daily on the palpebral conjunctiva and supplemented by hot poultices of rice starch.

The Presystolic Bruit.—Dr. C. G. Gibbes (Clinical Journal, July 12th), in a paper read before the Chelsea Clinical Society, arrives at the following conclusions: 1. In consequence of the different tension existing in the right and left ventricles, these cavities under the circumstances of mitral constriction do not act synchronously. 2. The base to apex portion of the right ventricular systolic wave occurs when the left ventricle is in diastole. 3. The right ventricular mus
Letters to the Editor.

DEATH FOLLOWING STRICTURE OF THE URETHRA.

63 West Fifty-fourth Street, July 25, 1899.

To the Editor of the New York Medical Journal:

Sir: I have read with great interest the letter of Edward A. Glasgow, M. D., interne of the Ensworth Hospital, St. Joseph, Mo., concerning a death following a stricture of the urethra, as the description closely tallies with that of so many cases which are treated in the free institutions in this city. The doctor asks the question, What could produce such a wholesale rapid destruction of tissue in a man who seemed only a few days before to possess unques tioned vitality? From the history of the case, it seems that the patient was a strong, healthy man, who entered the hospital eight or nine days before his death, suffering from a very small stricture of the deep urethra. Dr. Glasgow does not state whether this patient was suffering from retention or not.

If he was suffering from retention, he ought to have been relieved on that day, either by aspiration or by operation, instead of being allowed to go over until noon the following day, as during this time the kidneys secrete more urine than the bladder can hold, especially if the amount of urine already present at the time the retention comes on is added to this amount. In a case of this kind it is easy to see what a strain is brought upon the genito-urinary tract by pressure, and how easy it would be to wound the tissues about the stricture in the endeavor to pass instruments for the relief of the retention. It appears, however, from this letter that the patient was not suffering from retention at the time he entered the hospital, but simply from a tight stricture.

Impermeable strictures in strong, healthy young men, which suddenly give rise to sufficient trouble to cause them to enter a hospital, are generally of an inflammatory type—that is to say, there is a congestion about a tight stricture, rendering it much smaller. In this case rest in bed and treatment had probably reduced the congestion sufficiently to allow a small instrument to pass on the following day, but the letter reads that the small-sized sound was followed by larger ones until a No. 20 French was introduced; that the man’s urine then flowed uninterruptedly, and that all trouble was then supposed to be at an end, but that on the next day or so the penis, scrotum, testicles, and surrounding tissues began to swell until quite large proportions were assumed. The temperature went up to a high degree, and a gangrenous spot was noticed on the side of the penis, which spread rapidly, until, through sloughing, almost the entire organ was destroyed, and later the tissues of the urethra and penis became infiltrated with urine, and the patient died.

From this history it would appear that if the urethra had not ruptured before the passage of sounds had been accomplished, as it probably had not, the sudden increase in the size of the instruments from a small size to the 20 French had caused a rupture of the urethra in the dilated and thinned portion behind the stricture, and that this rupture had allowed the urine, infected as this fluid usually is in strictured cases, to extravasate into the tissues. The swelling of the surrounding tissues on the day after this instrumentation should have been, in my opinion, the signal for an immediate external perineal urethrotomy, with bladder drainage, and then the patient might not have been attacked with gangrene, and even if he had to a limited degree, life might have been saved by free drainage.

In a large hospital experience in a city institution, where the riffraff of New York are sent, such cases are not infrequent, and the patients often enter too late to be saved by surgical interference. They die of sep sis, due to urinary extravasation, urinary abscess, or gangrene. The wholesale and rapid destruction of tissue in this man, who had so shortly before appeared strong and healthy, is not surprising. He certainly lived for over eight days, whereas the majority of the patients coming under my observation, unless operated upon immediately on the first suspicion of urinary extrava sation, die even in a shorter time.

Ramon Guiteras, M. D.

THE TERM APPENDICITIS, ETC.; A REPLY TO DOCTOR ELLIS.

146 East Twenty-ninth Street, July 22, 1899.

To the Editor of the New York Medical Journal:

Sir: The modest little paper, The Term Appendicitis and Other Unscientific Words of our Nomenclature, published in the New York Medical Journal for May 20th, has been twice translated into Greek. One of these translations appeared in the June issue of Πρακτική Ημερολόγιον, a medical journal of Syra, one of the Cyclades Islands; the other in a periodical called Σάλτσης, of the island of Cyprus. A German version came out in the Deutsche medicinische Presse for June 22d. European papers and quite a number of private letters speak approvingly of the publication. Dr. R. Ellis, in his criticism in the New York Medical Journal for July 15th, is thus far the only adversary.

Musical people will tell us many things which they imagine they hear or see depicted when listening to a sonata or some other musical work. Something similar happens to my esteemed critic when he hears the dearly beloved word appendicitis. Dr. Ellis may kindly allow me to complement his interpretations. Appendix and appendicitis may mean or concern, indeed, a great many things, just as "I." may mean elevated railroad.

There exists a German students’ song about a dog whose tail had been cut off (Es lief ein Hund in das Refektorium, Observatorium, Laboratorium, Conservatorium). We learn by this song how many things can be understood by appendix: we may, for instance, mean cauda communis by it. If the word has a right to exist, there can be no objection to calling gonorrhoea appendicitis; we should then only have to define which appendix was meant.
When we begin to acquire knowledge of a foreign language we are apt to find many things amusing, as is the case with Dr. Ellis and the labyrinthine German word for appendicitis. I can speak from experience; it seemed to me exceedingly funny when I first learned the word literally. But let us see how this word compares with its equivalent in English: Wurm, Fortsatz, Entzündung—that this may be contracted ad libitum into one word—is inflammation of the vermiform appendix. The German term is composed of twenty-two letters, the English of thirty-four.

Würmfortsatzentzündung is used in Germany for and by laymen; in medical literature it is, as a rule, replaced by a Greek term. German medical literature, as regards onomatology, does not deserve the reproach made by Dr. Ellis when he says: "The German prefers his own words to international words"—quite the contrary, he is the most international in regard to technical terms. Dr. Ellis asks: "Why not accept a pure Latin word 'appendicitis'"? Si laetus, Doctore!

It is impossible to follow Dr. Ellis in his lecture on polyclinic and astylicin, because he assumes to know better Greek than all Greeks from the oldest times down to the present together. The small Greek schoolboy can explain why polyclinic is an impossibility, and astylicin is used instead, but I shall call to my aid Professor Kossmann, of the University of Berlin, a celebrated gynecologist and a doctor of philology besides, a thorough scholar in classical philology. He is one of the correspondents mentioned above. The word πύλη, he says, has been avoided in this combination, especially by the classical writers, for one reason, on account of the danger of giving rise to double meaning (πυλάεσ). In fact, the Greeks, as it stands to reason, know exactly when to employ ἀστυν and when to use πύλη. Police is, for instance, ἀστυνομία, but never πυλομοι. I could furnish many paradigmas. The Greek small boy might perhaps be amused to hear one calling himself πολιατρὸς instead of ἀστυνομ. Dr. Ellis, in producing evidence from Homer, Hesiod, and Sophocles, reminds me of a painful situation I once experienced. A refined American lady, wishing to practise French conversation, requested a friend of mine, a Frenchman, and myself to join her party at table in the boarding house which we happened to frequent together. One day the conversation turned upon blue laws, the law forbidding a man to kiss his wife on Sunday. The lady used an expression which would pass without objection among people with school French, which expression, except in grammar and lexicon, is, however, considered uncouth. When in the most careful manner we hinted that the word was not to be employed, the unfortunate lady knew better. Causa patrocinio non bona pejor erit.

I shall complement the criticisms of Dr. Ellis by quoting a just criticism against me.

Dietz, a master in the study of Romanic languages, has said: "The highest that can be attained by the etymologist is the satisfaction of having worked scientifically; there exists—in some instances—no security for absolute correctness. An insignificant note may, to his mortification, take away from under his feet what he had acquired by assiduous labor. Such will happen in all scientific investigation; in connection with etymological researches it is an everyday experience, even with the most ingenious man. Therefore let us observe modesty, even when everything seems to support our interpretations." I wish to make a practical application to myself: What I said about Wasserscheu as having been translated by some German into Greek is upset by a note by the editor to my paper in the Deutsche medizinische Presse: "The word hydrophobia was employed by Galen."

Dr. Ellis' suggestion to add the word cunonamia to the Greek vocabulary is superfluous, since the Greeks, who have more resources in using their own language than Dr. Ellis, use the word κυνόλογος when they wish to give the exact definition.

The German philologist of whom Dr. Ellis says, "Dear old fellow, I see him with his pipe and Stein," and further, "I see him drain his Stein," is Dr. Heinrich Zimmerer, professor of philology, the author of noble scientific works, not only treating of classical philology, but also of anthropology and ethnography. I have before me a work of his on the anthropology and ethnography of Syria and Asia Minor. He has written in the English language itself on American missions in Asiatic Turkey. He is an Orientalist who not only has learned a number of the eastern languages, such as Arabic, Turkish, and Armenian, like other scholars, by books, but speaks them all perfectly well. This proved to be of great value to him and to science when he traveled as a scientific investigator in Oriental countries.

As I mentioned in my paper, he has lived in Greece for years and speaks really living Greek. This prominent man and exceptional linguist is "the dear old fellow," as you call him, Dr. Ellis, with his pipe and Stein. I do not know what is his favorite beverage: as a good Christian he may not abstain from wine like the Mohammedans, and as a German he may indeed enjoy his Stein, but whichever of the two he drinks, I say to him: αἰσ ἄγειαν εὖρος.

Dr. Ellis says: "If all technical chemical and medical words were mongrel words like appendicitis and anthropometallism, the science would remain the same, in spite of poorly selected words, just as broken English may express exactly the thought of pure English, even though it may be harder to understand." The fact is that poorly selected words are a contradiction to science.

"The author," says Dr. Ellis, "makes an absurd mistake in supposing that there are 'malevolence and error' in regard to the Greek of to-day." I have to refer to my book Christian Greece and Living Greek, in which I have given conclusive evidence for this assertion.

A. Rose, M. D.

BECK'S OPERATION FOR HYPOSPADIAS.

37 EAST THIRTY-FIRST STREET, July 23, 1899.

To the Editor of the New York Medical Journal:

Sir: It was in the issue of January 29th of the New York Medical Journal that I described my new operation for balanic hypospadias, consisting in "dissecting free and extending the existing urethra so as to make it do the service of a new canal, instead of forming a new one," as had been the custom for centuries. The urethral orifice was sutured to the initial point of the freshened margins of the groove.

Previously to that, on October 4, 1897, I had demonstrated the new operation before the Deutsche medizini- nische Gesellschaft der Stadt New York (see report in the November issue of the New Yorker medicinische Monatsschrift, p. 597), where I first had suggested tunneling the glans by forming two flaps, lifting them
from the glans, and uniting their margins above the displaced urethra.

The illustrated reprints from the Journal were sent by me to all the eminent German and Austrian surgeons, and among them to Professor von Hacker, of Innsbruck. It gave me no little pleasure to receive a letter from so distinguished a surgeon as Czerny in May, 1898, wherein I was informed that my operation had been performed by him at his clinic in Heidelberg. On a trip to Germany during the early part of last summer I was glad to see a lively interest taken in it by other German surgeons of fame.

How great was my surprise, then, when I learned from a publication of von Hacker's (Beiträge zur klinische Chirurgie, August, 1898)—a whole year later—that he, "on the ground of experiments of his own," had reinvented my operation! To make the casus belli still more complicated, Dr. Breuer, of Bardenheuer's clinic at Cologne, published the same operation as "a new operation for hypospadias of the glans after Bardenheuer" in the Centralblatt für Chirurgie. Now the readers of the Centralblatt could witness the interesting spectacle of von Hacker and Breuer fighting each other over the priority for my operation (see No. 49 of the Centralblatt für Chirurgie, 1898). My name was, of course, carefully suppressed in this knightly feud, which shook the truthfulness of the old proverb: Duobus litigantibus terius gaudet—at least for me. To the credit of Dr. Breuer it must be said that, after a more thorough consideration of the literature, he kindly acknowledged my rights fully. But Herr von Hacker possesses the nostrum of immortality. He has, in fact, trimmed his epper so admirably well that it has been hailed through the leading journals as the von Hacker operation, while my original publications have hardly received any notice—of course! I should like to see what Herr von Hacker would do if he was treated reciprociter by an American surgeon.

C A R L B E C K, M. D.

P. S.—Since Herr von Hacker takes a most flattering interest in American ideas, I may take this opportunity of calling his attention to the fact that a short time ago I utilized the same principle for the female urethra, which permits of still greater displacement after being freed and dissected. In a case of old urethro-vaginal fistula, which had resisted previous attempts at closing it, the short anterior urethral fragment was exposed by a longitudinal incision and excised. Then the posterior urethral portion was dissected free and pulled forward, so that it could be sewed to the remainder of the orifice. May the great metropolis of Innsbruck offer the chances for giving this method also its proper staining!

A LIFE-INSURANCE SOLICITOR'S TRICK.

135 West One Hundred and Sixteenth Street, July 26, 1899.

To the Editor of the New York Medical Journal:

Sir: A man representing himself as a special agent of two or more life-insurance companies is operating among the physicians on the upper west side. His scheme is to appoint a doctor medical examiner for a company, and then suggest that he take out a policy, paying a part of the premium with the application. This information, embraced in a note in your Journal, may save some of us from being imposed upon.

Professor Garner on the Language of Monkeys.—
From the Columbus Medical Journal for July 5th we learn that at an informal meeting of the Columbus Academy of Medicine on the evening of the 5th inst., at Starling Medical College, Professor R. L. Garner, by invitation, delivered a lecture on the language of monkeys. Professor Garner has pursued the facts of science with such earnestness as to have no other ambition except to devote his life to this work. He described his methods of observation of the monkeys in the zoological gardens of this country and in the tropics, where he spent fifteen months studying the native animals in the heart of the dense jungles of western Africa. In his study and experiments among the apes in the zoological gardens, menageries, and in the jungles of Africa he says he has made his language intelligible to them, and that they have spoken to him and have been understood.

He said in part: “In studying the subject of monkeys they have always presented to me a serious scientific problem. It is not a theory, but a fact, that animals talk, and I can speak to them in their own language. I do assert that monkeys talk, that they communicate with one another by means of spoken sounds. I am not alone in believing that animals communicate. Those who confess that they communicate deny that they talk. I define speech as being any oral sound that is deliberately uttered with the preconceived purpose of conveying an idea from the mind of the speaker to the mind of a hearer. Any sound that performs that function is de facto speech. It is no longer denied that animals exercise the faculty of reason, of course not to the same extent that man does, but they trace out the relations of cause and effect and apply the solution to their own uses. They can not trace a long series of causes and effects, but they go sufficiently far to call it reason. Speech is materialized thought. It is thought made tangible and in such a manner as to be received by another. A German writer says ‘Speech is the body of which thought is the soul.’ Monkeys possess all the faculties that men do, although in a feebler degree—sensations of pain and pleasure, a limited sense of right and wrong, a vague idea of the rights of property or ownership, and a rudimentary conception of propriety and government. They hunger and thirst, sicken and die the same as men do. Then why is it thought strange that monkeys talk? I take it for granted that any animal that is capable of thinking is capable of expressing thought. Monkeys do talk. They communicate by means of vocal sounds.

“I am so frequently asked the question, ‘What first called your attention to this?’ ‘What caused you to study the speech of monkeys?’ To give you any one reason would be a difficult matter. I always believed that animals communicated and I grew up with this thought ripening and maturing as my own life did, though the evidence was not at first so apparent, nor was I prepared to demonstrate the fact. In the summer of 1851 I was in the Zoological Gardens in Cincinnati. I had before observed monkeys and tried to understand them, but I had never set about mastering their language. On the occasion of this visit I found a large rib-nose mandrill, or baboon, in a cage with a number of small monkeys who were kept in constant dread of this savage monster. The cage was divided into two compartments; through the partition was an aperture large enough to allow them to pass back and forth. A couple of these little monkeys were constantly on the watch and gave warning of the conduct of the baboon. It struck me that their speech gave such definite and exact information that the other monkeys were not left in doubt as to how they should act. They were quite informed as to the attitude of the baboon. I tried to distinguish and interpret this sound. Before the afternoon was over I was myself able to tell by the sound the nature of the conduct of the baboon. I immediately began the work. I began it then and there and continued it until the monkey house was closed. From that hour I believed it possible to master the speech of monkeys. I met with difficulties too numerous to recount. Among these one of the greatest was to remember exactly the sound made so that when I heard it again I could know that it was what I had heard before. After three or four years of incoherent effort to find out something about their language I decided to use the phonograph. I thought of this in the night and lay awake most of the night devising plans for the use of this instrument. I afterward went to Washington and arranged with Dr. Frank Baker to use the monkeys then at the Smithsonian Institution. At that time there were only two monkeys there. I secured a graphophone and on Sunday repaired thither with Dr. Baker and two or three others. I separated the two monkeys. They were of different species and even of different genera, but taking the male monkey into another part of the building I induced him to make some sounds. I recorded them, but did not know whether they were profanity or supplication. I took them into the room where the other monkey was and discharged them at her. They seemed to alarm her. They appeared to be sounds of anger. She gave evidence of understanding them. We could not tell whether her sounds were in reply or commentaries. They, however, were different from his sounds. I called Dr. Baker’s attention to this fact. Shortly after this visit I went to Chicago, where I selected a brown
MISCELLANY.

M. C. Baker.

_cebus monkey of which I made a clear and distinct record on a phonograph cylinder. This I carried to New York and reproduced it in the presence of another monkey of the same species. This monkey gave every evidence of understanding the sound. He wondered where the monkey was and examined the horn. At last he ventured to peep into the horn. He was evidently perplexed as to the cause of the sound. I had no means of recording the sounds that he made. I secured another instrument and recorded this monkey’s replies. I made about a hundred different records of the same species of monkeys; I confined myself exclusively to the one species. After some two years of almost constant work I was at last enabled to interpret nine of these sounds. The first sound interpreted signified food or the sensation of hunger. Now I found that by using this sound to them I could always elicit the interest of a monkey if he desired food. The next sound I interpreted seemed to have some relation to the feeling of the monkey during disagreeable weather. It was a sound of dissatisfaction, not only in connection with the weather in case of storm or wind, but was used when any other object afforded him displeasure or disquiet. By a repetition of these experiments I was enabled to verify certain interpretations. I tried to determine whether a certain species could understand the speech of another species or of other animals. I found that monkeys of a given species had a certain type of speech peculiar to themselves and that monkeys of another species did not understand unless shut up with them in a cage for a long time, and even then in replying they would speak in their own language. I know of but one exception to this. One acquired the sound for food. This was done in a period of six weeks. A monkey of this species would have understood it at once as being his sound for food. The circumstances under which it was done were such as to confirm my belief that he was trying to learn it. When I found his purpose I encouraged him to continue. It was witnessed by a number of persons. Dr. Ryerson, of Toronto, afterward bought this monkey and he told me that it retained this sound as long as it lived.

“The sounds of monkeys’ speech as reduced to the phonograph showed all the characteristics of human speech. It would take too long to tell how many of these experiments were performed. Some were very novel. Mr. Edison said he regarded them equally novel with the invention of the phonograph itself. I enlarged the sounds as one does objects under a microscope. I could amplify the sound unit and lengthen the intervals between them, giving the ear time to appreciate the details. I was able to reduce human speech to the same pitch and intensity as the speech of monkeys and reduce monkeys’ speech to human speech, only it sounded like a foreign language.

“I made records of Mr. and Mrs. Rooney, the two chimpanzees in the Cincinnati Zoological Gardens. I reproduced these records to Dr. Rosenthal, one of the greatest living linguists. He listened to them critically and pronounced them speech sounds, but of a low and barbarous type. He was not able to tell to what family of languages the sounds belonged, but agreed that they were speech of some kind and not a mere series of grunts or whines. When told what they were he listened again and again with deep attention and again pronounced them speech sounds.

“On one occasion when Professor John B. De Motte was lecturing in Washington I projected some of these sounds through the phoneidoscope and made them visible upon the screen in order to ascertain what they looked like. They presented all the characteristics of like phonetics in human speech, showing that the vocal organs that produce them have gone through the same mechanical action as in man. For the last eight or nine years he has continued to use these sounds in his lectures.

“On the subject of man and apes there is much to be said. It is not my purpose to discuss evolution, but it is necessary in connection with my work to call attention to the physical resemblances between man and ape. There is no reason why the great apes, as well as man, should not speak, for they are physically so nearly the same. In other words, the skeletons of man and of the great apes are so nearly alike that taking any particular part we find it difficult to distinguish whether it belongs to man or to the ape. There are four kinds of great apes, the chimpanzee, gorilla, orang, and gibbon. These constitute the anthropoid group, and there is but little difference in their skeletons.

“Concerning the skulls of these and all other animals, I have observed that there is a uniform graduation in the angles formed by the cervical axis and the facial axis when reckoned from a vertical line. This I have called the law of cranial projection, and the leading facts upon which it is based are these: When reckoned from a perpendicular the angle of the cervical axis is always coordinate to the angle of the facial plane on the opposite side of the upright line. In man both of these axes are in an erect position. In an ape, with its crouching habit, the chin is thrown forward and the cervical axis at a like angle. As we descend the scale through the monkeys, lemurs, and lemuroids to the reptilian forms the two angles continue to widen in exactly the same degree, and as these angles widen the vocal powers lessen in scope and degrade in quality until in the reptile they are lost in a mere hiss. The craniofacial angle widens in the same manner and the gnathic angle the same. In like manner the longitudinal, vertical, and transverse axes of the brain coordinate so that knowing the exact degree of any of these angles it is possible to reckon all the rest from them and from this basis to determine with precision the vocal scope of any animal—that is, to tell the range of sounds that he is capable of making and the degree of precision with which he can modulate them. Through the whole range of nature, from man downward, the gnathic index may be regarded as the vocal index.”

A Cincinnati Doctor Knighted.—According to the Cincinnati Lancet-Clinic for July 23d, Dr. A. Ravogli, who has long been the Italian consul in Cincinnati, has been erected a Cavaliere by King Humbert of Italy.

The Columbus Medical Journal.—Dr. J. U. Barnhill, for five years associate editor of the Columbus Medical Journal, has been appointed editor on the retirement of Dr. John Edwin Brown.

The Royal College of Surgeons of England.—We learn that Sir William MacCormac has again been elected to the presidency. This makes his fourth incumbency of the office.

“What might have been!”—In our issue for March 25th we cited from the Grèce médicale a story of a fraudulent charge of rape in which the girl, to rupture the hymen, had passed an egg into the vagina, where it was
discovered and broken in the process of examination by the physicians. The Medical Age for July 10th quotes the same story from a French source and remarks: "If the egg had been fecundated, and it had been allowed to take its course to maturity uninterrupted in the vagina, there is nothing of what interesting questions in legal teratology would have arisen."

Las Vegas Hot Springs, N. M.—Dr. William Curtiss Bailey, the medical director of this New Mexico health resort, who is also the local observer for the government weather bureau, has sent us an extract from his report for the year ending May 31st. The place is situated in the "dry belt," and is recommended as a health resort for persons who need a large amount of sunshine, dry air, and a medium altitude, with no extremes of heat or cold. As regards temperature, however, it is stated that on eight days of the year the thermometer registered over 90° F., and five times, at night, it fell below zero. In the dry air of Las Vegas, probably a temperature of 90° would not be objectionable.

A Christian Science Druggist's Fate.—We quote the following from the Pharmaceutical Era for July 13th: "The Christian Science fantasy has claimed many dupes and victims. These have generally been those individuals who would be cranks anyhow upon some subject or other, so that it is only occasionally that the crimes of this sect have come to public notice through their effects upon the general public. It is therefore very startling to learn that one of a class of men who, it would seem, would be the very last to be duped by this fanatical faith, has succumbed to it and lost his reason in consequence. Christian Science does not believe in drugs; therefore a druggist who is also a Christian Scientist must be regarded as a strange anomaly. It is a most incompatible mixture. Such a druggist can not practise what he preaches in both professions. If he is true to the Science he can not sell drugs; if he can not sell drugs he must starve, and this is just the position of an unfortunate druggist in an Illinois town. He has gone crazy over Christian Science. He lost his business because he advised his customers to leave drugs alone; and not only this, but his sister and niece have also become demented upon the same subject, and the former has died in an insane asylum."

The Mysteries of Medical Nomenclature.—Judge for August 5th has the following:

Patient: "I say, doctor, just what is this grippe anyway?"

Doctor: "Why, my good fellow, that's the name we doctors have for everything nowadays but appendicitis."

Patient: "Ah! And what is appendicitis?"

Doctor: "Why, that's the name we have for everything but grippe."

Encyclopedic Knowledge.—Dr. F. D. Bird (Intercolonial Medical Journal of Australasia, March 20th), in an address to medical students, said: "There are two extremes of students—the one who will not take the trouble to acquire knowledge; he, of course, drops out early, but his anti-thesis is always acquiring knowledge, until he becomes a walking encyclopaedia. Now, I would warn you against becoming an encyclopedic student, overweighted with loads of learned lumber, which you will not be able to use quickly and effectively as your profession will require of you. This student is apt to think that his quantity of knowledge has the quality of wisdom. There is such a thing as being too knowledgeable, and the frame of mind in which such a student is apt to get reminds one of the horse that Canon MacColl tells about: 'A friend of mine,' says the Canon, 'once shared the box seat with the driver of a stagecoach in Yorkshire, and, being a lover of horses, he talked with the coachman about his team, admiring one horse in particular. "Ah," said the driver, "but that 'oss ain't as good as he looks; he's a scientific 'oss." "A scientific horse," exclaimed my friend. "What on earth do you mean by that?" "I means," he replied, "a 'oss as thinks he knows a deal more nor he does." Now, we all think as this scientific horse thinks, but the encyclopedic student excels the most scientific of horses in this respect.

"Encyclopedic knowledge, carefully garnered in years of seeing and thinking, is a magnificent mental asset, but it is otherwise when stowed away rapidly and not thought over as it is received. The sixty-ton guns of learning score heavily at times, but it is the quick-firing mental armament that you especially require in our profession."

The Diplococcus of Pregnancy?—The Medical Age for July 25th commends the following anecdote to the consideration of Professor Schenck and his enthusiastic followers: A clergyman, walking on the outskirts of his parish one day, found one of his parishioners whitewashing his cottage. Pleased at this novel manifestation of the virtue that is next to godliness, he complimented the man on his desire for neatness. With a mysterious air the worker descended from the ladder and, approaching the fence, said: "That's not exactly the reason why I'm a-doin' this 'ere job, your worship. The last two couples as lived 'ere 'ad twins, so I says to my missus: 'I'll take and whitewash the place so as there mayn't be no infection.' You see, sir, as how we've got ten of 'em already."

Death of Sir Alexander Armstrong.—The Lancet for July 22d announces the death of Sir Alexander Armstrong, F. R. S., LL. D., M. D., F. R. C. P., etc. Sir Alexander, as a fleet surgeon of the navy, spent five years continuously in the expedition of the Investigator in search of Sir John Franklin in the arctic seas. In the course of this voyage a northwest passage was made out.

The Perils of a Public Vaccinator in England.—The Lancet for July 22d says that at the Hereford Police Court on July 3d an architect was summoned for neglecting to have his child vaccinated. The public vaccinator stated that he sent to the defendant a notice respecting vaccination, but that he did not call upon him, as he received a letter from the defendant saying that he "kept a revolver for the benefit of public vaccinators." The defendant was eventually ordered to have the child vaccinated in a month.

Sport and Philanthropy.—According to the Lancet for July 22d, the Duke of Westminster has presented the sum of £10,000, the amount won by his horse Flying Fox in the Eclipse Stakes at Sandown Park last week, to the Royal Alexandra Hospital, Rhyl, of which his Grace is president. The Lancet commends this excellent example to other owners who race for love of the sport and not for "filthy lucre."

WHY SOME SEvere CASES OF APPENDICITIS END IN RECOVERY WITHOUT OPERATION.*

By J. H. CARSTENS, M.D.,

DETROIT.

All of us have seen severe cases of appendicitis in which patients unexpectedly recover. If, in such a case, a surgeon has been called who advised an operation, he will be laughed at forever after by the patient, and such an instance will always be pointed out to show that in severe cases patients will get well with any kind of treatment or even without any treatment.

Those of us who advocate usually a prompt operation are perfectly helpless if such a case is pointed out to us. We can not deny that it occurred, that the operation was urged, but that the patient would not submit. All we can say is that it is a very rare occurrence. Formerly I explained it by showing that the appendix would become attached alongside of the cecum or the intestine, sometimes even to the sigmoid flexure, and thus rupture into the bowel and heal without much trouble.

During the last year I came across several interesting cases in which there were peculiarities of the anatomical relation of the appendix, which explains how in severe cases rupture into the cecum can easily occur, with prompt and permanent recovery.

In fact, the whole question of appendicitis has always seemed to me to be purely one of anatomy. As I showed in an article a few years ago, published in the New York Medical Journal, you will find in all cases where there is inflammation of the appendix that there is a stricture (or several). Generally it is at the junction with the cecum. Sometimes the valve is closed, at others the mucous membrane is so swollen as to more or less close up the opening. In all my experience I have seen only one appendix attacked with inflammation, where the canal was of the same size or where the opening in the cecum was larger than the rest of the appendix. In other words, when the appendix has such a shape that anything can get into it easily and also get out easily, there is no danger of appendicitis, as appendicitis is brought about by the inability of the appendix to empty itself, whether the contents are a little fecal matter, septic mucus, or a foreign body.

This, it seems to me, is the plain, simple, and whole aetiological factor. I will admit that the appendix is more liable to inflammation than other parts, on account of its poor blood supply. There is a greater tendency to it, but the poor blood supply never is an exciting factor.

During my past year's experience, I came across two peculiar cases. They were well marked and characteristic of the case with which patients in severe cases might recover, so I thought a few words on this subject would be interesting.

The first case was that of Mr. I. B., who had had three attacks, the last being so severe that he was finally frightened into submitting to an operation in the interval. He was operated on May 27, 1898, in the usual manner. Opening the abdomen and bringing the cecum into view the appendix was found in a peculiar position, as indicated by the drawing. Fig. 1 shows the external appearance; Fig. 2, a cross section of the condition. It will be noticed that the point of the appendix for the extent of fully an inch, was adherent to the cecum, beneath the peritoneum. There was absolutely no peritoneum between the appendix and the cecum. Hence, it can be easily seen that, in a case of this kind, if the inflammation took place at the distal end (which it naturally would), how it would fill with pus and finally rupture into the cecum, simply going in the direction of the least resistance. Muscle is a soft tissue. It easily breaks down. It offers less resistance than the peritoneum, which is a firm, strong, and fibrous body and requires a good deal of force to break. Not only that it breaks less easily than muscle, but the amount of plastic lymph which would be thrown out by the peritoneum itself, when it is irritated, would strengthen it and still more tend to cause rupture into the bowel instead of into the abdominal cavity.

The other case, that of Mrs. M. C., who had two attacks and was operated on May 7th, is identical, except that there was no loop as in the first case. The appendix was lying flat along the cecum over the whole extent and absolutely had no mesentery whatever. It was about two inches and a half long, lying between the muscular coat and the peritoneum of the cecum.

* Read before the Michigan State Medical Society, May 5, 1899.
The peritoneum had to be split up to the whole extent (two inches and a half) and shoved back a little on each side, so that the appendix, without any peritoneal covering, could be easily enucleated and removed; then the two flaps of the peritoneum could be brought together over the bed where the appendix had been. In order to strengthen it, another row of Lembert sutures was used. Fig. 4 shows a cross section.

These two cases explain how a case of appendicitis with the most acute symptoms, such as fever, sepsis, etc., can suddenly break, and all the symptoms subside in a very few hours without any outward manifestations being present. There may not be any diarrhea, and the small amount of pus passed into the cecum will become mixed with fecal matter and not be observed at all, and we wonder how it is possible that the patient can recover.

In such cases we are guyed by our conservative friends and told not to be too hasty with the knife.

This is the simple point I want to make in my paper, but it might be interesting to say a few words about the technics of operations. In interval cases, clean and aseptic, the usual incision is made. The location of this incision differs. A number have been advocated, but all have their good points. I prefer the outer edge of the rectus or the blunt separation of the oblique muscles without cutting them. In acute cases, we can not pay so much attention to the line of incision, and it is often better to get near the crest of the ilium. When the abdomen is opened and the appendix loosened from its adhesions, tie the mesocolon with one or two ligatures, according to its size, and loosen the appendix so that you have the appendix entirely free from its attachment. Cut through the peritoneum all around and strip it back, then hold the denuded appendix with a forceps, or, as I prefer, with the fingers, close to the cecum and cut it off. You must hold it tight, as there is a great tendency to retraction, and if you let it slip out of your fingers, the contents of the bowels may contaminate the cavity. With fine catgut sew the muscular coats of the appendix together; three or four stitches will do it. Carefully wipe the end, for a little contamination may have taken place. Cover the stump with peritoneum and, if that is not enough, depress this part and cover it once more with a row of Lembert sutures. You now have a firm, smooth surface. There is no danger of rupture of the bowel, and if there is an abscess in the stump, it will break into the cecum, as I have shown before, and not into the abdominal cavity. The abdominal cavity is sewed up in the usual manner (in layers, with catgut).

In the purulent cases, sometimes the appendix is entirely sloughed and hence can not be removed. Some cases you can treat as you do interval cases, but, as a general rule, in suppuration cases, simple ligation of the appendix near the cecum is enough. You have the abscess cavity any way, you need drainage, you save time, and your patient gets along just as well. In these cases you need gauze or rubber drainage, sometimes both, and the abdominal incision should be closed with the figure-of-eight silkworm suture, but a sufficiently large opening
should be left. I would rather have an abdominal hernia than a dead patient from lack of drainage. Sometimes I have had to take out one or two stitches afterward, not having left a large enough opening.

From January 1 to December 31, 1898, I have had thirty-three operations for appendicitis. That is, strict cases. Those in which the appendix was removed in conjunction with the tubes or ovaries, or uterus, or for any other reason, are not included in this list. The list is as follows:

Thirty-three cases—two deaths; thirteen cases between attacks. Seven cases of appendicular colic. Thirteen cases during attacks, with rupture and high temperature, with pus, and more or less general peritonitis.

The High Aims of the Physician.*

BY BEVERLEY ROBINSON, M. D.

The Climatological Association is no small fraternity of little men with no great end and objects in view. Already by its work it holds an honorable position among other medical associations. Thanks to the tender care of those who watched and nurtured it at its inception—

*The Presidential Address delivered before the American Climatological Association, May 9, 1899.
here it is, gentlemen, that we would speak, and that, too, in no uncertain tones, of the character of the physician. Let him continue to be in the future as he has been in the past, the saving help in time of need of the sorrowful and sorrowing one; but let him also be as he is now, and should be more and more, the guiding hand of the people in all matters relating to public health.

We want our cities and towns to be thoroughly cleansed, the sewerage to be carefully and properly attended to, our streets to be well lighted, our health-board regulations to be governed with all scientific safeguards, looking to the common good and alike for the poor as well as for the rich. It is for us to insist upon, every day and at all times, the evils of our tenement-house system and the moral turpitude and physical debasement which necessarily proceed therefrom. Of course, I recognize that broad-minded, generous, noble citizens within and without our profession have already come to the front and have given their work, their time, their money, their influence to change these canker sores of our Greater New York, of our Empire City. On the other hand, political greed and ambition have stood in the way of a grander, larger, more extensive, and far-reaching work. The day will come, however, and none too soon, when with our electrical railways and through trains on every city line, our numerous bridges over both North and East Rivers, the man of small means will be able to give his wife and family and self the contentment and joy of a real home, where peace and moral worth and elevation of thought and action dwell continuously.

In the family relations, also, the chosen doctor who is to guide and direct, will be selected not because he knows everything pertaining to medical and surgical science, but because he among other men knows the most. If there are, as there must frequently be, occasions when the specialist's advice is sought for and required, he will stand by as the guardian of the family's first interests; he will be requested not to allow any narrow views to control the situation; not to permit any interference, medical or surgical, to be carried out unless with his entire approbation and indorsement. And the patients will select their physician because of his well-known, well-grounded intelligence, his previous long and honorable record of good and faithful work accomplished before his fellows and in the light of day—knowing as they will and must that he does for them not merely as he does for himself, but rather as he does for those he loves best in the world—heart within and God o'erhead. To repeat once again, for the physician as for other men, the noblest aim of his ambition should be to establish character. To lose it is to be as it is related of a renowned French orator: * "When Mirabeau, in the consciousness of the possession of the most masterful genius of his time, rose to speak in the National As-

* The Outlook, September 10, 1898, p. 133.

 semble, he became aware that his absolute past was standing beside him and mocking him. His vast power, honestly put forth for great ends, was neutralized by a record which made belief in him almost impossible. In bitterness of soul he learned that genius and character are bound together by indissoluble ties, and that genius without character is like oil that blazes up and dies down about a shattered lamp.""

On the other hand, to gain it and firmly establish it, is to thoroughly fill the soul's best longing. Then he may become ideally, at least, such an one as Dr. Butler, "Master of Trinity," describes Gladstone in the finest memorial address which his death called forth:

"Critics, friendly and unfriendly, might weigh the varied elements of his rare intellectual structure; its range, its subtlety, its mastery over men; but the verdict of multitudes and of nations has been rather this: He gave us many gifts; but the most precious and the most enduring was himself, his character. He lived and labored with God before his eyes. He had the fear of God before him, and made a conscience of what he did. He loved righteousness and hated iniquity. His heart was with the poor and the wronged and the down-trodden, and dear was their blood in his sight. It is this conviction which at this hour draws us 'with the cords of a man' and makes us all of one mind." *

In Joseph H. Choate's splendid oration, delivered by him at the unveiling of the statue of Rufus Choate, the great lawyer and advocate, in the new courthouse of Boston, the speaker said: "And first, and far above his splendid talents and his triumphant eloquence, I would place the character of the man—pure, honest, delivered absolutely from all the temptations of sordid and mercenary things, aspiring daily to what was higher and better, loathing all that was vulgar and of low repute, simple as a child, and tender and sympathetic as a woman. So let the statue stand as notice to all who seek to enter here that the first requisite of all true renown in our noble profession—renown not for a day or a life only, but for generations—is character." †

In the Harveian oration on The Influence of Character and Right Judgment in Medicine, ‡ delivered before the Royal College of Physicians of London on October 18, 1898, by Sir Dyce Duckworth, the speaker said:

"We are perhaps too much disposed to commemorate the scientific achievements of our great men, but let us not be unmindful of their characters. We know that genius is not always coincident with the highest moral or spiritual perfection, but when both these qualities are graciously combined in any one, we feel that we are in the presence of a truly great man, of one who becomes a personage and a power for good in his day and gen-

‡ Lancet, October 22, 1898, pp. 1097-1043.
eration. In such a profession as ours we can never afford to lose sight of the preponderating influence of character in all who join our ranks and have to minister to every grade of our common humanity.

And further on says Dr. Duckworth in eulogizing the immortal Harvey: "The day in which it has been affirmed that there is a gulf fixed between physical and spiritual science is, I think and hope, fast drawing to a close."

As Willis observes, Harvey "seized every opportunity of giving utterance to his sense of the immediate agency of the Divine in Nature." He had no fear either of the processes or the results of research. We can imagine his approval of the following sentences in the Religio Medici, which he must have read: "There is no danger to propound these mysteries, no sanctum sanctorum in philosophy. The world was made to be inhabited by beasts, but studied and contemplated by man; 'tis the debt of our reason we owe unto God and the homage we pay for not being beasts. . . . Those highly magnify Him, whose judicious inquiry into his acts, and deliberate research into his creatures, return the duty of a devout and learned admiration. Therefore:

"Search where thou wilt; and let thy reason go, To ransom truth, e'en to the abyss below; Rally the scattered causes; and that line Which Nature twists be able to untwine. It is thy Maker's will; for unto none, But unto reason can He e'er be known."

Again speaks Duckworth: "Harvey himself best summed up his great characteristic and guiding principle in a concise sentence, which might even now be fitly inscribed on his sarcophagus, and it is this: 'I avow myself the partisan of truth alone.'"

That was the great moral of his life—truth eternal, ever to be sought for, to be held, and to be passed on.

Some men, perhaps, in what I have tried to outline, may find things to criticise or take exception to; they may say all this is very well, but is it not Utopian, impractical, impossible? I presume this is true, but it is equally true of all idealism, of all perfection. And yet what we very much need to-day in our lives is this very idealism. We have enough and more than enough of the practical. Our daily routine is essentially practical. Most of us are obliged to work, to labor, to save. We know that in this way, and this way alone for the majority of men, success is ultimately reached. Ignorance and deception and false ideas of life and its purpose surround us. Workly applause, the desire to have fame at any price, and even though it be acquired by means that are unworthy; the constant, ceaseless endeavor to outstrip one's fellows and get ahead, may capture those who are filled with a narrow, selfish ambition. But is such a struggle to be imitated or admired? Is the reputation thus acquired ever enduring? I am sure it is not. The men whose fame is perennial, whose deeds are praised and glorified after they have gone and disappeared from sight, are those whose memories give us always a thrill of enthusiasm which awakens what is best within us, and tells of a goal to win that does not pass away and is not purely chimerical.

With the rapid growth of specialization, with the constant search for new things, with the ever-increasing scientific investigations in so many directions, with the augmented opportunities and necessities of chemical, microscopic, and bacteriological findings, the older practitioner is apt to think that his previous education and training have become time-worn and obsolete. But is it so? Should we not insist and believe that they are all the more valuable? Medicine is no art of yesterday, nor is its science altogether modern. The ancients have handed us down much, very much, that is still true, that always will be true. We, in our day and time, have added to the store of valuable knowledge. And this, too, must remain. Many things we once thought were good and would endure have been found useless, and hence are now neglected or forgotten; but so it is, or will be, with much that is now highly thought of and esteemed. With this conviction is produced a wise conservatism of thought and action. The older practitioner is conservative, and rightly so, not because he dreads new discoveries, not because he would stand in the way of legitimate progress, but simply because he knows that "all is not gold that glitters," and that shams and frauds are many; that enthusiasm needs to be controlled; that knowledge does not come in a day, and that the sifting of the wheat from the chaff is always a labor of time and care, prolonged, continuous inquiry and repeated observation. Reverence for men and things of the past must be kept alive—not followed and adhered to with the praise and laudation of a fetish; but, nevertheless, not derided and abandoned altogether because other things are newer and, consequently, to many minds, more attractive.

How often do we hear the reproach made to the older practitioner that he has become antiquated; that he is no longer abreast of the times; that the younger man must know more because he is fresh from the schools, and hence he has the latest and best equipment! But is this often true? Is not the knowledge bought of and through experience something that experience alone can give and justify? How many prescriptions are uselessly written and unwisely taken that come from the junior members of our profession! How many surgical operations are performed that may add to the building éclat of our brilliant young operator, and yet, if he could but see and thoroughly understand how small, if any, is the ultimate advantage for the patient to be derived from them, would not his hand be withheld? Would he not be content to advance more slowly but more surely, and certainly more conscientiously?

Happily for us to-day, medical education is higher in its intellectual grasp than it was a decade or two ago.
A longer, more arduous ordeal is of necessity gone through to obtain the right to practise, and for this reason errors of doing because of mere ignorance do not occur so often. The people who swallow nostrums, who are cured by friends, by acquaintances, or over the drug counter, are not, as a rule, the educated, trained men and women. Fortunately, no doubt, the too-confiding victims are the silly and the weak, the ignorant and thoughtless, those who imagine that knowledge and information come by sleight of hand or sudden inspiration. The best of us know absolutely the contrary. To these misguided and foolish ones I would point unerringly to the myriad of patient, laborious workers whose life and deeds blazon forth the one truism of constant, unremitting toil. Tell not for bread, not for fame, not for worldly rank, not for popular applause, not for greed, but simply, as de Toqueville writes, for duty to be done and well done. Faraday, Huxley, Tyndall, Pasteur, Helmholtz, Lister, Virchow, Sanderson, Bastian, and countless others "who spurned delights and lived laborious days," prove it and glorify it.

One of the retorts which the specialist sometimes makes to the general practitioner is that without his help the patient would not, could not, recover. He firmly believes it is his medical or surgical skill which gets the success in curing the sufferer which would not otherwise be attained. But we may say to such a one: "Friend, the body of man is not perfect, physically or functionally, as a rule—and assuredly this statement is correct after middle life is entered upon—therefore it is not wisdom beyond a certain point to try to reach a standard that we shall not probably secure; indeed, that is scarcely possible, unless the personal sacrifice be very great, or other conditions are made morbid, or hurt, through our foolish efforts." The latter is very frequently the attitude of the general practitioner, who with his broad appreciation of all bodily ailments knows when to say Halt!—when or how to interfere. It is not always given to him to be able to do just what should be done, if it requires special skill or training to do it well, but he always should be the guiding hand, the referee to whom any grave or even apparently small matter is taken, and by whom ultimately it is decided. Of course, in the process of time and with increased success in certain lines of practice, men, as they grow older—and particularly the better informed and more skillful and capable ones—will gradually drift, as it were, into doing where some chosen field of work lies. But there is a sort of natural law which governs, and which ultimately produces the best results. But this is very different, and far better than the plan which tells a man that he should do this or that sort of work before he can possibly know what he is best fitted for, and without the long preliminary training which makes him a worthy applicant for ultimate and legitimate great success.

One great result, if no other, is assuredly achieved. Medical men do not see at every turn in the road some slight local defect which they wish to remedy with mere local means. They become broader and larger. They note the interdependence of all our organs, of all our functions; they generalize as they should, and from numerous isolated facts grasp mighty laws which govern. This is the correlation which almost invariably exists in our bodies, sick or well. It is for us to recognize it and follow it fully and rationally wherever it leads us.

Anatomy, normal and morbid, teaches us many things; but to see in mere structural conditions or changes everything, and not allow for the wide influence and omnipresent functional disturbance, is surely to narrow very much our power for good. How often do we go to the autopsy room to find multiplied diseased conditions of organs, and yet, when the history of the case is carefully analyzed, are we not astonished that with such, if they really have primary importance, all previous health or enjoyment would have been wholly impossible? On the other hand, do we not frequently see the autopsy made with greatest care without detecting any obvious diseased condition? Nevertheless, the patient's life has been one long series of disabilities and sufferings, and, to crown them all, death comes. The vital force, the latent energy, the dynamic, essential thing is also the unknown, and probably always will be.

The great physician of to-day should be the man who thus sees and reads Nature. He should be the one, of course, who studies the influences of climate and soil; of environment; of habits and customs; of professional and business lives; of light and heat; of winds and dust and dirt; of moisture and dryness, and all such influences for health and disease. But in his mental appreciations should also be the idea of thought and feeling and emotion; of cares and sorrows; and when he thus becomes, can he ever thoroughly abrogate the true missionary spirit? Is not the physician the one who has got to have it in the mere nature of things? Is he not obliged to minister to the soul as well as to the body? I do not mean or intend to convey that the physician is to teach men any of the things which pertain merely to sect, or to try at any time to clothe himself with a priestly mantle. I do mean, however, that by patience and sympathy, forbearance and long-suffering, and absolute rectitude in all he does and all he hopes to attain, he should be the highest ideal it may be given on earth for a man to follow. If such be the man, outside and beyond his purely professional calling, the great and good physician becomes the great and good citizen. His civic virtues are many; he obeys law and order; he points the way to a higher and nobler moral sense; he works not for hire, but for all men's best good. He points and directs the way in all social reforms. He is but a reflex in the body politic of everything that men should hold righteous and of good report. Immorality has no place near him; indecency of thought and word should not be countenanced by him. Reverence for Na-
ture, Nature's laws, and the overruling God—the moving, essential spirit of all law in this world and in the next—are his guiding star. Self-sacrifice for men, which he inculcates beyond any price in his own life and example, becomes then, and always must and should, what leads men more than everything else to recognize the brotherhood of men and the saving help of Him who died to make men holy.

Having endeavored to show briefly how essential it is for the physician to establish character; how important it is also for him to educate his heart and mind so that he may ever be in close touch of sympathy and affection with his patients; how true it is that he should never lose sight of the fact that he too in his person must ennoble, if possible, all civic virtues; and how, finally and above all, he must inculcate by his example and doctrine the purest aspects of Christian living, I still have a word to add for the scientific and practical sides of medicine—their relations and interdependence. To-day we think a great deal of science—its advancement, its wonderful conquests. We feel as though things, to be true, must be proved, and in matter of proof we are apt to abide too closely by the results of mere laboratory research; and even before the test of time has thoroughly shown their possible falsity or shortcomings, to allow ourselves to be guided and directed by them. Everywhere and at all times nowadays we hear and read of the omnipresent microbe and of his fearful ravages. Seldom do we hear to the fact that he is often a very innocent or inoffensive factor in our bodily ailments. Whenever we have given him a form, size, aspect, immediately we infer that he always represents trouble and disaster. At least such is the attitude too frequently of the profanum vulgus; and likewise, let it be candidly admitted, of the not overwise scientist, who forgets that the art of medicine is the practice thereof, and that this art is quite as jealous a mistress and needs to be served with just as much fidelity and patience and brains as the science upon which the art is in part based.

In many diseases of an infectious type* the rôle played by bacteria, it seems to me, has been misinterpreted. They, in themselves, are not the causative agents of these maladies, but are rather a frequent accompaniment of the septic process, and may act as mere carriers of contagion. It is not difficult to understand, therefore, that when once the septic action is begun by the presence and influence of a poisonous principle of the contagious or infectious disease, such change may take place in the liquids and tissues of the body as to promote the rapid production and development of different forms of bacteria, with more or less characteristic features.

And after this manner may be satisfactorily explained the almost indefinite production or reproduction of the septic poison in any one of the diseases referred to. Let us beware, however, of confounding the really pernicious substance with an agent whose influence, to say the least, is at times probably but indirect and secondary. Once more, the bacterium is the abode of the poison, not the poison itself. This dwelling place, as it were, may remain the same for quite a period of time, and through an uninterrupted succession of many different individuals. It may also be destroyed or changed by the use of methods which occasion separation of the poison from the microbe, or else which destroy the virulent principle by decomposing it, or simply neutralizing its pathological action.

There are experiments to show that salicylic acid and carbolic acid, while excellent preservatives and antimicrophytics, are perhaps not always disinfectants in the strict sense of the term. In other words, the true poison of virulent disease will remain unaltered by their action even though lower organisms are destroyed and the power taken away by which their reproduction is effected.

If this is true of the noxa of virulent disease, it is probably true also of the poisonous principles of zymotic affections in general. In these diseases, therefore, when by the most perfect and thorough employment of anti-septics we have taken it for granted that we have destroyed their special cause of transmissibility, we have possibly tended rather to preserve it intact than to annihilate it. And what applies to the acids mentioned above, as types of a large class of so-called disinfectants, may apply equally well to many other substances of different chemical and physical properties, but which are coordinated by many physicians with the former on account of a similar destructive action which they exercise over lower forms of life.

It behooves us, in this as in other difficult or problematical subjects of medicine, to liberate ourselves from preconceived or too absolute theories which impede our progressive march in the path of exact knowledge. The following conclusions, taken from the address of Charlton Bastian, in which he attempts to refute the too exclusive views of the upholders of the germ theory of zymotic diseases, contain even at the present day some wholesome truths:

"1. The virus or contagium of some of these diseases, whatever it may be, does not exhibit the properties of living matter.

"2. There is the extreme improbability of the supposition that this whole class of diseases should be caused by organisms known only by their effects.

"3. The facts of the sudden cessation, periodical visitation, and many of the other phenomena of epidemics, however difficult they may be to explain upon any hypothesis, seem to oppose almost insuperable obstacles

to the belief that living organisms are the causes of such epidemics of specific contagious diseases."* 

To Bastian's conclusions, pronounced twenty-four years ago, I would now add citations from the Huxley lecture on Recent Advances in Science, by Professor Rudolph Virchow, delivered last autumn in London on a memorable occasion. Virchow writes: † "With the discovery of parasitic animals conjecture became fact, and nothing was easier than to generalize this fact and assume the presence of independent organisms in each contagious disease. . . . It may be said that the contagious nature of disease shows suspicions of bacterial origin, but it should not be simply called that, although it allows the conscience to sleep. Some of the most important contagious diseases have succeeded in resisting the struggle to find in them a parasitic contagium. For example, many have been the sanguine hopes of finding the parasite of syphilis and as many have been the failures; the coccus of gonorrhoea alone has been discovered, the bacterium of syphilis remains a desideratum. You will remember the certainty with which it was expected that a parasite was the causal agent of variola—more than one was found, but none pathogenic. In hydrophobia all appearance seemed to promise that it would prove to be a microparasitic disease. Its contagion is undoubted; the vaccine has been prepared, and yet no one has been able to cultivate a specific bacillus. The same may be said of some other specific diseases. Painful as it may be, one can do nothing but observe. Perhaps the pathogenic bacteria will be found, but as long as they are not discovered all assumption is useless if not dangerous. To have learned this is to have made a mighty stride in the biology of disease."

"It was a happy inspiration," writes the editor of the Lancet, ‡ which led the authorities of Charing Cross Hospital to invite Professor Virchow to deliver the Huxley lecture on the occasion of the opening of the medical session.

"They could not have better honored the name of the eminent man whose medical education was obtained in their institution than by linking it in this manner with that of the foremost living exponent of pathological science. . . ."

"Perhaps the most interesting portion of this lecture was the exposition of parasitism and the great extension which has been given to this in the discovery of the minute parasitic agents which excite the infectious diseases. Professor Virchow did well to remind us that the reaction of the tissues and organs to the bacterial poisons forms an essential part of these diseases, and he, perhaps wisely, bade us remember that there may be some infections in which bacteria have no share."

In corroboration of, as well in advance, in my judgment, of Professor Virchow's ideas I would cite from a paper read by Professor Martins, of Rostock, at the annual meeting of the German Naturalists and Physicians at Düsseldorf * on September 19, 1898, on The Cause of and Predisposing Conditions for Disease.

Professor Rostock says: "What predisposition or tendency of the organism gives the opportunity for the vegetable parasite to gain a foothold we are no nearer knowing than before, yet this is the important element in the origin of disease.

"There was a time in the inception of modern pathological anatomy when the discovery of the distinctive pathological lesion of the disease was thought to have brought medicine nearer to the ens morbi, to the essence of the disease. When it was found, for example, that hepatisation of the lungs was characteristic of pneumonia, it was considered that a distinct step had been made toward knowing the entity of inflammation of the lungs. Now we know the bacterial cause that sets up the hepatisation, but we are no nearer knowing why one man is afflicted with it, another not, although both seem to have been exposed to similar conditions and in the mouths of both pneumococcus may be demonstrable. . . ."

"If exposure to microbial infection was always followed by disease, then bacteriology would have given us an explanation of the origin of disease. Infection and disease are by no means correlative terms, and the difficult question of susceptibility comes in as an important element to make us realize that we are still a long way from the explanation of specific pathogenesis. The study of susceptibility and its causes is to be an important occupation for the pathologist of the twentieth century, and much more is to be hoped from a widening of our knowledge of predisposing conditions to disease than from the further discovery of specific bacterial causes. This advance of knowledge, however, will come from no one-sided bacteriological hygienist, but from those who have studied profoundly the conditions of disease as they are."

Let us then erect our laboratories, promote scientific research, be wisely liberal and generous to those who with microscope and reagent and vivisection set the pace in a measure for the clinician. Let us not, however, ignore the claims of the latter to our fealty and lasting trust when more science will not avail us much. I can not do better here than to quote from an address delivered by Professor William H. Draper before the Association of American Physicians.*

"We must pursue science," says Dr. Draper, "so as not to imperil the progress of art, and we must cultivate art as if science were not so much its mistress as its handmaid."

"We may wisely recall and apply the answer which Iphocrates, the Athenian general, is said to have made

THE EFFECTS OF INFLUENZA UPON THE EYES.

By HENRY S. OPPENHEIMER, M.D.

About a year ago Dr. Turney wrote in the London Lancet: "Influenza is now so hackneyed a topic for medical writers that mere mention of it has become almost a punishable offense." And then he went on and wrote an article upon this subject.

It seems to me that, until the microbe producing this ailment is reproduced under the conditions laid down so clearly by Koch as necessary to prove its title, the last word upon this subject will not have been spoken.

The subject of influenza is of interest to all of us, as we are surrounded by it. It is being studied carefully by many observers, and described accurately. While its manifestations in the eyes are comparatively few (when we consider the millions of cases which have been seen in the last decade), the reported observations have been so interesting and so numerous actually that a mass of material is at our disposal of which I intend to give you an abstract. To begin at the most external and least important lesions, we have absence of lid reported by Ehrlich and Landolt.‡ So far as one can judge by the descriptions, these may have been cases of severe hordeolum, for hordeola are very commonly seen during or shortly after attacks of influenza, and numerous reported. I will say here, in order to save time, that all cases of which I shall speak in this paper occurred during or shortly after influenza, without other diseases being present or suspected, unless expressly mentioned here, and in all the inference is therefore that they were due to influenza or its effects.

Finzi * saw a case of herpes zoster of the lid. Hemorrhages into the conjunctiva are common, and are probably nearly all brought on by coughing. The catarhal type of conjunctivitis is so often observed that it only needs mention.

Pflüger † has seen croupous membrane on the conjunctiva, also Valude (this on a phthisical stump upon which an artificial eye had been worn). This case will be referred to again later. Coppee reports diphteritic membrane; Rampoldi, subconjunctival abscesses.
Keratitis dendritica is reported by Gatman; punctate keratitis by Pooley, Webster, and Weeks. Badal and Galezowsky report eruptive and suppurrative keratitis. Pans* saw a man with pterygium develop a central ulcer of the cornea with general infiltration of that tissue. Dianoux saw serpigious ulcers in two eyes (in different patients) develop after a purulent cyclitis, of which more later on. Adler reports one case of keratitis parenchymatosa—the only one I have found on record in this connection. Herpes febrilis of the lips was seen in an epidemic in Hamburg in twenty-five per cent. of all influenza cases, and so it was observed in the cornea a number of times very naturally. Phlyctenulae of the cornea are seen so often at all times that it seems to me difficult to say that in certain cases influenza produces them. Considering the effects of influenza on the nasal mucous membrane, we shall not be surprised that the tear duct and sac are frequently affected. Pooley saw stenosis of the duct. Ehrlich reports cases of purulent dacrocystitis; also Lindner,† Badal, and Fage.‡

Galezowsky reports a case of episcleritis (the only one I could find). Bergmeister and Shopringer* saw suppurative and non-suppurative inflammation of Tenon's capsule. Fuchs [*] saw one beginning on the fourth day of the influenza, with exophthalmus, swollen lids, loss of motility of the eye, and eventually two openings into the orbit, giving vent to pus which showed pneumococci. Gazis reports a similar case;§ Ehrlich, one of inflammation of Tenon's capsule and one of orbital cellulitis. Valude, in a domestic aged twenty-six years, after the "grippe" had passed, found pneumonia, followed by premature birth of her child, and false membrane on the conjunctiva (above alluded to) on a phthisical stump over which she had worn a shell. This eye went on to panophthalmitis, and the pus evacuated contained diplococci, streptococci, and the white staphylococci. Bull (C. S.) saw, on the second day of the influenza, a phthisical eye develop orbital cellulitis and panophthalmitis. In the third week the eye was enucleated. Four days after this (in the fourth week) the patient died with meningitis. No pus was found in the sheath of the optic nerve on autopsy. (This report is without microscopical findings.) Panus † reports an eye going into panophthalmitis which had previously shown granular conjunctivitis and pannus.

Badal reports iritis and iridochorioiditis. The suppurrative processes reported are very numerous. They are in all probability of embolic origin. Lagen‡ gives a case of bilateral embolic iridocyclitis which developed suddenly on the eighth day of the disease. Complete blindness in four days. Eversbusch, one of purulent choroiditis on the ninth day, followed by panophthalmitis and perforation. The eye was enucleated and showed the Staphylococcus pyogenes aureus in great numbers, also infections emboli in several vessels of the uvea. Hosch,* one case of purulent iritis and hypopyon. Horstmann (Leyden and Gutman) cites cases of Grief (Pfueger, Berthom,† and Wicherkiewich,‡ thus collecting quite a variety of suppurative processes in the eye. Natanson, an interesting case with pleuro-pneumonia and bilateral embolic iridochorioiditis. Blindness on third day, death on fifth.

Andrews (reported by Pooley) saw five children between seven and nine years old, after the influenza had subsided, develop iridocyclitis, either suppurrative or non-suppurative. All had coughs; no head symptoms. Two eyes were lost.

"Alt," of St. Louis, saw seven cases like the above also in children; only these seem all to have been suppurative. In three both eyes were lost, in four only one. Dianoux reported to the Société française d'ophthalmologie, in the session of May, 1898, an epidemic in Nantes, during which he saw six cases with hypopyon and purulent cyclitis with increased tension (a rare thing in cyclitis in all cases. It was double in two patients only. Dianoux thinks the choroid and vitreous were not implicated because the patients could see the hand. He calls attention to the fact that none of these eyes were healthy before this attack. There was tertiary syphilis, cataract, or post-operative aphakia, etc. His treatment consisted in evacuating the anterior chamber once or twice a day. He reports all these eyes "cured" but two (above alluded to). In these two serpigious ulcers appeared in the cornea (after repeated evacuations of the anterior chamber) and "nearly destroyed the eyes." Dianoux also saw one case of septic hamorrhagic retinitis. I saw two cases of hemmorhage which injured the eyes—one in a man of thirty-five years, who had never been ill before he took the "grippe" with cough. He was recovering when he came to me showing extensive ecchymosis of lids and conjunctiva, both ocular and palpebral. This had come on overnight. Movements of eyes and pupils were normal. In the left eye the disc was hazy, the veins greatly enlarged. V. = $\frac{3}{4}$. No color scotoma. R. eye V. = $\frac{3}{4}$. Diagnosis, papillitis of the left eye, probably due to bleeding into the nerve sheath.

My second case was in a man of twenty-seven years, who complained of pains in chest and back from "grippe." He had noticed his right eye growing dim on the day before he came to me. In and around his right optic disc were splashes of hemorrhage, with exudation at the edge of the nerve. An expert reported to me that he had found him perfectly healthy, but perhaps slightly anemic. No venereal disease. Uses

neither alcohol nor tobacco. He had no sickness since childhood. V. O. D. s; O. S. s.

In influenza the nerves are frequently affected. To begin with the optic nerves, we have in them inflammations both in the eye and back of the globe. Of the retrobulbar neuritis Bull reports a case in a man, sixty-two years old, who was ill nourished. On the fourth day of influenza there appeared suddenly a central, absolute scotoma, about 30° in all directions from the centre. Examination by ophthalmoscope gave negative evidence throughout. The scotoma disappeared for form, but remained for colors. Other cases of this pericocular neuritis are given by Hansen,* Bergmeister,† Stoewer,‡ Ehrlich,* Antonelli, || all followed by partial or complete atrophy. Metoxas, one with hemerolopia and final atrophy.

I saw a man of thirty years, who felt everything moving before him one afternoon while at work. The next morning he was blind in the right eye. This was somewhat prominent and painful when pushed back into the orbit. Pupil dilated ad maximum. Media clear. Nerve and the retina between the macula and disc hazy. V. = 2/1. No color scotoma. Eye pains on looking upward. This and double vision due to paresis of inferior rectus. Diagnosis, retrobulbar neuritis. Has just recovered from influenza. No other complaints except nervousness and a rapid pulse. Denies clues and shows no trace of it. Uses no alcohol or tobacco. Of neuritis optica, as seen by ophthalmoscope in the eye, there are also many reports. Weeks, Hansen, Bergmeister, d'Eperon, Pooley, also Ehrlich, Königstein, Denti, Novelli, Vignes and Lebeau (cited by Knes), Sehorgan, etc. Snell* reports cases ending in atrophy more or less complete. Horridge, a case of bilateral neuritis. Remak, one who, on the fourth day of the disease, had four convulsions in one hour, followed by loss of vision and optic atrophy.

Bergmeister reports cases of "simple and inflammatory atrophy of opticus, with loss of color sense and concentric limitations of the field."

Grady saw a woman, who had influenza and pneumonia, become suddenly blind in the third week of the disease. She had a small central area of vision left. This improved, but was followed twelve days later by a sudden manifestation of right bilateral hemianopsia, which remained permanently.

Gifford reports the case of a man who, during gripe, had sudden violent pain in the occipital region followed by bilateral right hemianopsia, which remained unchanged for three years.

Only a week ago I last saw a man of fifty years, who came to me on November 27th because his right eye "had a black spot in it," as he put it. I found a somewhat irregular central scotoma of about 10°, which gradually disappeared under simple tonics, as he grew stronger from the depression following influenza. He had no visible lesion in the eye.

Landsberg* reports a similar case in a woman who, when convalescing, suddenly noticed a central scotoma. She recovered under the use of strychnine. He also tells of a man who, on the fourteenth day of the gripe, became suddenly blind in one eye without visible lesion. He had a narrow field and was totally color blind. He regained normal vision in eleven days under daily injections of pilocarpine.

The cyanopia reported was probably of central origin, but will perhaps be as well alluded to here as elsewhere. Hillert† reports two cases of chromatopsia after gripe. One man, pale and ill nourished, with normal fundus and visual acuity, after persistent vertigo, saw everything blue. On iron and bromide of sodium his vision became normal in two weeks.

The other case was in a woman who, at the height of gripe, saw yellow for two hours. This blue vision means probably an exhaustion of the nerve centres, or possibly the effects upon the brain of some toxine. There are only six such cases reported, so far as I can find. Three were in neurasthenics, one in a case of fatal nephritis, one in a case of intermittens larvata, and the sixth in influenza. Another case of yellow vision is reported by Hillmans. The yellow vision produced by santonin is well known.

The nervous system seems to be specially selected by influenza. I have given some of the lesions affecting the second cranial nerve. As a matter of fact, all nerves sending branches to the eye are at times affected. Paralysis of accommodation has been seen by Andrews, Pooley, Webster, and Weeks. Uhlthoff gives a case of paralysis of accommodation, with progressive ophthalmoplegia externa and symptoms of bulbar paralysis. Badal saw a man, thirty-three years old, without rheumatism or lues, develop, during convalescence from a severe attack of gripe, diplopia due to paresis of all the muscles supplied by the third nerve, excepting the superior rectus, sphincter iridis, and muscle of accommodation. A second patient of his, a man of fifty-seven years, had paralysis of right external rectus. Recovery was rapid.

Above I reported paresis of the inferior rectus. Van der Bergh reports paresis of rectus superior and two of the abducens. Stoewer, one of the levator and rectus superior. Gayet, one of double ophthalmoplegia externa, without the levator palpebrae being affected. Gutman, one of one-sided ophthalmoplegia externa. Grief, one case of paralysis of the left sympathetic, with enlargement of the threoid, prominent globes, heart's action rapid and irregular, in which ptosis of the right eye developed. Chase noticed gradually increasing prominence of eyes in a woman, twenty-

eight years old, after gripe. Her health appeared good. The exophthalmus lasted for two years.

Colley reports a case of Graves's disease after "gripe." Schirmer, one complicated instance of right unilateral complete ophthalmoplegia, with anesthesia of the right face and scalp, paresis of the right masseter and temporal muscles, and of the tongue of the same side. This seems to have been a lesion, probably hemorrhagic, at the base.

Sedan tells of a girl, seven years old, who, after a severe nosebleeding during gripe, was taken with a passing blindness. Bock gives a rare case of bleaching out of the eyelashes in a young lady.

The ciliary muscle seems to be the most frequent of the eye muscles affected. Its paresis is usually bilateral. It may exist without mydriasis, and together with difficulty of speech and swallowing. Such cases closely resemble the effects of diphtheria, and, like these, they usually disappear entirely. Next in frequency comes paralysis of the sixth, then of the fourth. Individual muscles may be partially or completely paralyzed. There may be external or internal ophthalmoplegia on one or both sides. The vitreous is at times affected. Gutman reports a case of hemorrhage into it. Fresh opacities of the vitreous were seen by Eversbusch and Gillet de Grandmont. Another by Magnus, which he calls "retinitis proliferans." Attacks of acute glaucoma were observed by Adler, Eversbusch, Knies (double), Gradenigo, Rampoldt, Stuffer, Badal and Fago, Bom, and Webster.

This shows a rather extensive list of clinical observations of eye troubles during or shortly after influenza. When we try to explain to ourselves the way in which these are produced, we are led naturally to divide them into different classes. To begin with glaucoma, we have so many reports of cases of glaucoma occurring in predisposed persons, among diseases reducing their strength, such as erysipelas, pneumonia, pericholangitis, extirpation of a large ovarian cyst, severe catarrh of bladder, bronchi, or alimentary canal, that we are warranted in the conclusion that any morbid condition tending to greatly reduce the strength of patients predisposed to glaucoma can bring on an attack of this malady, and we need ascribe no specific effect to influenza in the production of these outbreaks. This same lowering of strength will account for the lighter grades of paresis of the eye muscles, especially of accommodation. In the hemorrhages into different parts we have the changed condition of the blood as the probable responsible factor; and this without taking into account the septic emboli, which will be alluded to later. No specific effect is necessary to explain these hemorrhages. We have them in all diseases affecting seriously the condition of the blood; as, for instance, in diabetes, icterus, severe loss of blood, albuminuria, anemia, leucemia, etc.

In the purulent uveitis and orbital cellulitis, panophthalmitis, etc., emboli containing pyogenic cocci are evidently the original factors. How much the Pfeiffer-Canon bacillus is responsible for these lesions, or for influenza in general, I am not prepared to say. The cocci have usually been found, the bacillus mentioned rarely. Add to this the fact that the cultivated bacillus has never produced influenza symptoms except in monkeys, and we must conclude that the claim for the bacillus is not yet proved.

There remain, in conclusion, the severe nervous troubles to be accounted for. To my mind, when they can not be explained by the occurrence of hemorrhages, they seem to be caused by malnutrition, using the word in its broader sense, combined at times with localized edema. As an example of the effects of malnutrition I will only mention the epidemics of night blindness observed in Russian prisons and barracks during the fast of six weeks ordained by the Greek Church. During this fast meat is abstained from entirely. As the general condition of these patients is usually at low ebb, and their hygienic surroundings are of the worst, this additional reduction of nutrition produces the result of hemeralopia and other disturbances. Weiss found that these sufferers recovered by rest in bed and the best diet the hospital afforded, without other treatment of any sort.

Thus, to my mind, the lack of appetite, the vitiated functions of the digestive apparatus, the consequent changes in the blood, lowered nutrition, together with the great depression of the heart's action (which is in all probability due to toxines produced by the yet undiscovered causative microbe), will account for the profound impression upon the nervous system which is so commonly observed, and explain the chromatopsia, scotomata, inflammations and paralyses of the nerves and muscles supplied by them.

Hæmoglobinuric Fever.†

By Edward E. Field, M.D.,
Norfolk, Va.

It is my intention to call attention to a peculiar form of malarial disease now known as hæmoglobinuric fever, a condition which, as its name indicates, is characterized by the excretion by the kidneys of the coloring matter of the blood. The close resemblance of some of its symptoms to those of yellow fever makes it doubly important that we be able to differentiate the two diseases.

The disease is known in this State as "yellow

chills” or “hemorrhagic malarial fever,” in North Carolina as “Roanoke yellow fever,” and in Alabama as the “yellow disease,” and is of especial interest on account of its recent origin, rapid results, and high rate of mortality. The terms “Roanoke yellow fever” and “hemorrhagic malarial fever” are misleading, for while there are symptoms of the disease in question which strongly resemble both, still there are very distinctive points of difference between them, as will be shown farther on. The disease, on its appearance in the Roanoke Valley, was at first supposed to be yellow fever, and when afterward it was discovered to have a separate and distinct individuality, the term “Roanoke” was prefixed to distinguish it from the true yellow fever.

The term hemorrhagic malarial fever is equally erroneous, for in any malarial fever we may have hemorrhage from any and all mucous surfaces without the concomitant yellow hue of the skin, hematuria, and rapid onset of the disease.

In this connection Thayer says: “The association of hemoglobinuria with malaria has long been recognized. The condition is often referred to as malarial hematuria, which may indeed exist, though in many instances actual blood-corpuscles are not to be found in the sediment of the urine, or, if they are found, are present in very small numbers; the condition is then due to the presence of a blood-coloring matter—a true hemoglobinuria. The coloring matter is always present in the form of methaemoglobin.”

Authorities agree that malarial hemoglobinuria is uncommon in temperate climates; and in the more malarious and tropical regions its distribution is remarkable. In some districts, as Algeria, where pernicious malaria prevails, it is of unusual occurrence; while in others, as in Sicily, Greece, and the West Coast of Africa, it is very common.

It is stated by Thayer and other observers that persons attacked by hemoglobinuric fever are subjects of chronic malarial disease. While this is probably generally true, it has not been invariable, clinically speaking, in the cases which have come under my observation. Some of these patients seemed to be attacked outright, although they had been residents of a malarious district. Certainly two of my patients appeared to be in perfect health up to the time of attack. The symptoms are as follows:

Malaise and languor, coldness of extremities, chilly sensations along the spine, blueness of the lips and fingers, headache, severe pains in the regions of the liver and kidneys, extreme nervousness, small and feeble pulse, pale and slightly furred tongue, and the bowels usually constipated.

This stage is of extremely variable duration, and is followed by the hot stage, in which the pyrexia may reach 104° or 105°—the skin being also subjectively hot, the eyes injected, watery and bright, the conjunctiva being sometimes yellowish. The headache and pain in the hypochondriac and lumbar regions become more intense, and the patient voids as much as eight ounces or a pint of peculiar coffee-colored urine every ten or fifteen minutes. Thirst becomes excessive, and nausea, with vomiting of black matter closely resembling black vomit, occurs. Partial deafness comes on. A yellow hue spreads over the skin until the entire surface is of an orange color. Delirium at this stage is a frequent though not constant symptom. At a variable interval the sweating stage comes on with or without a decrease of the fever. The yellowness of the skin increases, so that in many instances the clothing of the patient is stained yellow wherever it is saturated with perspiration. There is usually a decline of all the other symptoms; the urine is less in quantity and paler in color; nervousness not so marked; thirst less intense, yet the patient is left in an extremely weak and often semicoma condition. The tongue at this stage is covered with a heavy dirty yellow coating. A peculiar sweetish smell, resembling that of a ripe pumpkin, has been developed in all cases which have come under my observation. Symptoms of uraemic poisoning often occur at this stage, and the patient may die from their effects or from exhaustion in a few hours from the onset of the chill. Otherwise there is a slight return of the symptoms during the next twenty-four hours. In favorable cases there is a slow convalescence. In one of my cases temporary suppression of the menses preceded and followed the attack.

In fatal cases, if the patient does not die from the hemorrhagic or uraemic poisoning during the first thirty-six hours, the result is brought on by exhaustion in the next three or four days.

**Yellow Fever.**

Gives immunity from a second attack.

**Malarial Hemoglobinuria.**

Gives no immunity, but predisposes to a second attack.

Disease of towns and seashore. Is confined to certain localities.

Disease of malarial districts, and not of towns and seashore. No high degree required.

Requires temperature of 80° F. for its development.

Occurs at all seasons of the year, preferably in autumn.

Never occurs after frost.

Not infectious.

Urinary excessive; port wine or coffee-colored; high specific gravity; feebly acid.

Usually follows an attack of intermittent fever.

Infectious. Urine scanty and high colored.

No previous history of intermittent fever.

Jaundice very rapid.

No hemorrhage, except from kidney.

Faget’s law of rising temperature and falling pulse.

Usually a remission in a few hours.

Yellow hue comes on slowly.

Violent headache nearly universal.

Hemorrhage from mucous surfaces.

Characteristic flush of forehead and fiery look of eyes.

Negroes not exempt.

Negroes exempt.
I have grouped together the symptoms of yellow fever and malarial haemoglobinuria to show the points of analogy between the two diseases (see page 279).

The points of analogy between the two diseases are black vomit, yellowness of skin, high degrees of pyrexia, and constipation.

The points of distinction between haemoglobinuria and ordinary bilious remittent are as clearly defined. In the latter the slower onset, the less rapid and less intense jaundice, the absence of black vomit, the haemorrhage occurring from any mucous surface, the tongue coated with a heavy white fur, all sufficiently show that these two diseases, while allied, are not identical.

Manson says of the urine: "If the characteristic dark-brown urine of a haemoglobinuric case be left for some time in a urine glass it separates into two well-marked layers: an upper of a clear though very dark port-wine tint, and a lower—perhaps amounting to one half or one third of the entire bulk—of a somewhat brownish-gray color, and consisting of a sediment in which an enormous number of hyaline and haemoglobin tube casts are to be found, together with a large quantity of brownish granular material. Epithelium is also met with; but blood-corpuscles may be entirely absent, or very few in number. With the haemoglobin there is also an escape of the serum of the blood, for the urine turns almost solid on boiling; and for some days after it has gained a normal appearance the urine will still contain albumin, though in gradually diminishing amount."

This agrees pretty closely with my own observations.

The morbid anatomy of the kidneys shows them, if examined at an early stage of the disease, to be enlarged and congested, the tubules blocked with haemoglobin infarcts, the cells laden with yellow pigment grains and the corpuscles with black malarial pigment. If the patient survives for three or four weeks and then dies of uraemia, the appearances are those of large white kidney.

It will readily be seen that where there is a pre-existing lesion of the kidney, we have to do not only with a haemoglobinuria but with a true haematuria, the weakened epithelial walls allowing a transudation of the cellular elements of the blood.

The first step in the progress of haemoglobinuria is haemoglobinæmia, or the presence in the blood current of haemoglobin set free by the destruction of the red blood-cells. This condition would occur in a minor degree in the physiological destruction of the red blood-cells did not the liver transform the haemoglobin into bilirubin.

Where the red blood-cells are rendered less resistant by any cause—as, for instance, a chronic malarial condition—the sudden onset of a strong exciting agent, as a malignant group of malarial germs, destroys them so rapidly that haemoglobin in excessive quantity is set free in the blood.

The liver, which in all probability is torpid, is unable to convert this amount of haemoglobin into bilirubin, and consequently the work of excretion is thrown upon the kidneys, which elaborate it in the form of urolasthenoblobin. The irritant effect of this body is often so great as to produce grave lesions of the kidneys and permit the transudation of a number of blood-cells and their débris, thus producing a true haematuria.

Of course when there was a preexisting lesion of the kidney this is more probable. The skin also assists in the excretion of haemoglobin, but whether as methaemoglobin I have been unable to ascertain. The inability of these organs to remove the haemoglobin rapidly enough causes the deposit of yellow pigment in the various tissues, the resulting jaundice being both haematogenous and hepatogenous.

Landois and Stirling say: "The bile acids in the blood dissolve the red blood-corpuscles. The haemoglobin is changed into new bile pigment, and the globulinike body of the haemoglobin may form urinary cylinders or casts in the urinary tubules, which are ultimately washed out of the tubules by the urine."

I would remark that quinine, particularly the sulphate, given to prevent a malarial paroxysm, often produces haemoglobinuria. Given the proper predisposing conditions, quinine seems to furnish as readily exciting a cause of haemoglobinuria as does a crop of malarial parasites.

As to the specific form of the plasmodium which is the genetic factor in malarial haemoglobinuria, authorities are not agreed. Manson states that "the specific character of the germs has not been accurately determined, further than that they are small and rarely sporulate in the peripheral blood, belonging doubtless to some form of the crescent-forming malignant type." Thayer says that the blood in malarial haemoglobinuria, if the process occurs in an acute infection, shows the aestivo-autumnal parasite.

In only one of the cases which have come under my observation was the blood examined for the plasmodium. This case showed only the plasmodia of the benign tertian or quartan type.

Unfortunately, the therapy of haemoglobinuric fever is very unsatisfactory, the mortality in the most successful hands being extremely high, probably not less than fifty per cent.

Many practitioners give quinine freely under the mistaken impression that it is the best remedy because it is the best antiperiodic, losing sight of its causative agency in the production of haemoglobinuria.

In my opinion it should never be given until all signs of haemoglobinuria have disappeared, and then only tentatively, discontinuing its administration upon the first appearance of bloody urine.

The treatment which was most successful in the cases which came under my notice was relief of the
constipation by salines, the withholding of quinine, morphine hypodermically for the great pain and restlessness, cold to the head, and administration of arsenic to prevent recurrence of the malarial paroxysm.

Cantlie and Guice recommend the use of oil of turpentine in doses of ten drops every three or four hours for the hematuria, but I believe it to be unscientific and harmful to irritate the overtaxed kidneys with so violent a diuretic. Theoretically, the flushing out of the kidneys with a soft water would seem to be indicated.

The other treatment should consist in keeping up the strength of the patient by the usual methods, allaying irritability of the stomach, giving liquids only, and preventing as far as possible a recurrence of the paroxysm.

THE PATHOLOGY AND ETIOLOGY OF RHEUMATISM,
WITH SOME REMARKS ON TREATMENT.
BY CUVIER R. MARSHALL, A.M., M.D.,
DETROIT.

The term "rheumatism" has long been the cloak for many diagnostic sins. In this particular instance fashion has seemed to sanction a somewhat prevalent disregard for scientific accuracy in nosology, to such an extent that painful affections of the human anatomy, no matter where seated or how manifested, are not infrequently classified, with dignified nonchalance, as rheumatism.

Recently, however, the popularity of this ancient malady has been quite seriously imperiled by the appearance of a new candidate for public favor. In order to retain the confidence and esteem of his patients, or to maintain an unblemished popular reputation as a diagnostician, many a physician has yielded to the temptation to class commonplace disorders as "la grippe." The grippe is now the fashionable disease; it is the proper thing to have the grippe in season. The physician who is so conscientious that he will not thus characterize his cases of coryza, pharyngitis, laryngitis, bronchitis, gastritis, and even that virile though inconvenient ailment, specific urthritis, is not up to date, and is very liable to be invested by his neighbors with the sobriquet of "old fogy."

But no matter how generally the term rheumatism may have been misapplied, and however much the etiology of the disease has been obscured in the vast and cloudy maze of pathological night, like the poor, we have it with us always, without regard to locality, season, climate, age, sex, or previous condition of the victim. Right here we are confronted with a notable example of the fact that pathology has not kept pace with the vanguard in the march of therapeutic progress. The rational treatment of this disorder, although well defined and amply sustained by volumes of clinical experience, smacks vehemently of mediæval empiricism.

It is reasonable to acknowledge that the pathology and etiology of rheumatism are still somewhat enshrouded in mystery. It has long been held that lactic acid, in some way, by its presence in the blood causes rheumatism. Under improved methods of investigation this idea seems to have met the inevitable fate of most medical theories. Lapine found that the blood of a person dying from rheumatism gave a neutral reaction, while Bouchard discovered that the synovial fluid of rheumatic sufferers is acid in reaction, although there is no evidence to show that such reaction is due to the presence of lactic acid. Not even the slightest trace of lactic acid could be detected by Salomon in the venous blood of persons suffering with acute articular rheumatism; yet clinical observers are aware that acid sweats in this disease are not of infrequent occurrence, even though it has not been shown that the reaction is due to the presence of lactic acid. In fine, we may concede that the existence of lactic acid in the economy is a predisposing cause of the disease, but there is no conclusive evidence that it is the exciting cause.

Among the more recently advanced theories those of Reinhard * and Mordhorst † are worthy of note. The former says that rheumatism is an infectious disease, following a traumatic lesion of particularly the oral mucous membrane, through which the infectious agent obtains access to the system. His treatment consists, therefore, in the prophylactic cleansing of the mouth at frequent intervals. Mordhorst has undertaken a series of chemical experiments from which he draws the following inferences:

"The phenomena of rheumatism rest upon the accumulation of urate spherules in the connective tissue and cartilage.

"The alkalization of juices of connective tissue is due to sodium carbonate and not to the bicarbonate or phosphate.

"Acids favor, in the extreme, the precipitation of the spherules, while alkalies prevent this precipitation.

"Sodium salicylate favors the transformation of urate spherules into urate needles. This explains why this salt cuts short the inflammatory process, but predisposes to relapse, which is due to the needles' persistence in the tissues.

"Urate spherules are naturally subject to oxidation; urate needles are not.

"Sodium carbonate and bicarbonate do not directly hasten solution of needles, but probably favor oxidation of spherules. These salts are best given in mineral waters free from lime and containing sodium chloride and carbonic acid."

The published opinions of Satterlee and Haig are

* Müncheh. med. Woch., September 12, 1898.
† Centralblatt für innere Med., No. 19, 1898.
sufficiently well known to justify only a passing reference to their talented authors in this connection. The idea of Angel Moncy is similar to theirs, since he believes that rheumatism is due to the presence in the blood of elements resulting from nitrogenous tissue metabolism—i.e., the products of fatigue, which induce a toxic blood state.

The various efforts to isolate a specific micro-organism which might be demonstrated to be the aetiological factor, so long sought for, have so far proved unavailing. Chvostek has expressed the view that a specific organism could not cause the disease, *per se*, but that it must be regarded as the pathological manifestation of the poisonous action of certain toxines of various bacteria. These toxines, he believes, find entrance into the circulation through the tonsils or the intestinal mucosa. Guttmann and Sahli found staphyloccoci in the joints, kidneys, and pericardium, while Leyden discovered a diplococcus. Birch-Hirschfeld, Triboulet, Bouchard, Charrin, Singer, and others have found various bacteria in the joints of rheumatic individuals. It would be vastly easier to arrive at some definite conclusion if each of these observers had reported finding the same bacterium, but the results of their work have been seriously depreciated by the finding of a varied assortment of streptococci, staphyloccoci, diplococci, bacillii, etc.

The following clinical facts are patent and must have some bearing upon the subject of aetiology. One of the known exciting causes of acute articular rheumatism is chilling of the surface of the body by exposure to cold and dampness. As a result, the normal acid secretion of the skin is checked or suppressed. Retention of the acid formerly eliminated in the normal perspiration reduces the alkalinity of the blood, a condition which is a prominent feature of the disease. Reduced alkalinity of the blood plasma may also follow the ingestion of foods containing a high percentage of acid, or the absorption of the products of acid fermentation (lactic, etc.) in the gastro-intestinal tract. What, then, is the result of a reduction from the normal alkalinity of the blood plasma? Chiefly this: Nutrition is inhibited by diminished oxidation, as illustrated by the experiments of Loeb, of the Chicago University, who found that the addition of a weak alkali to the water in which they are growing will accelerate the development of invertebrate larvae. In other words, increased alkalinity favors oxidation and increased nutrition, while reduced alkalinity of the plasma means diminished oxidation and consequently retarded nutrition. As animals become immune to the action of bacteria the alkalinity of the blood is increased, while pathogenic microorganisms flourish most luxuriantly in a plasma of a low degree of alkalinity. Defective oxidation, and hence retarded nutrition, are most generally observed in warm and damp climates. The clear, cold, and dry air of winter acts as a stimulant to those processes which are then so much accelerated that many of the phenomena characteristic of rheumatism are checked or fail to appear.

Here we seem to have come upon an insurmountable obstacle in following up the question before us. Like the many-hued butterfly, when pursued by the ardent school boy, it seems to have passed just beyond our reach. But so far as we have gone we have been able to assure ourselves that rheumatism is a disease characterized by a state of reduced alkalinity of the blood, and caused by certain toxic agents whose character and identity are as yet a mystery. We are somewhat in the position of the great Newton, who said, shortly before his death: "I do not know what I may appear to the world, but to myself I seem to have been only like a boy playing on the seashore, and devoting myself now and then to finding a smoother pebble or a prettier shell than ordinary, while the great ocean of truth lay all undiscovered before me."

The successful treatment of rheumatism, as we understand it to-day, was elaborated in the school of bedside experience. In the acute form there is no remedy at all comparable with the salicylates. True, they are objectionable in one or two minor respects, but what excellent remedial agent is not chargeable with the same shortcoming? The salicylates of the alkalies are well adapted to the treatment of rheumatism, especially in the light of our present knowledge of the disease. They are well known as antiseptics, while the absorption of their bases increases the alkalinity of the blood plasma which thus becomes an indifferent culture medium for pathological micro-organisms. The consensus of professional opinion warrants the statement that the prompt and systematic administration of full doses of the alkaline salicylates is the only safe plan to adopt in the treatment of the acute type of articular rheumatism. Pain is thereby relieved, the temperature is controlled, the tendency to the development of endocarditis is checked, and the local artithritic inflammations are alleviated. In a few days the disease is virtually mastered and the prospect of recovery is by no means remote. In an experience of nearly fifteen years the writer has rarely had occasion to administer a narcotic anodyne for the relief of the pain of acute articular rheumatism. There is one precaution to observe when prescribing the alkaline salicylates, and that is to insist upon having dispensed only the purest drugs obtainable. Nausea, tinnitus aurium, and delirium are apt to follow the ingestion of impure salicylates of sodium and other alkalies.

In a well-marked, acute adult case, the treatment should be instituted by ordering from fifteen to twenty grains of pure salicylate of sodium—or a mixture of the salicylates of sodium and ammonium—to be given every second hour. Should gastric irritability arise, the drug may be taken dissolved in carbonated water, either plain or flavored with syrup of sarsaparilla.
A very excellent preparation, adaptable to varied conditions of age, sex, and severity of attack, is the elixir of manaca and salicylates made by Parke, Davis, & Co. It contains thirteen grains to the fluid drachm of the combined salicylates of sodium, potassium, and lithium, together with ten grains of manaca, itself a valuable alterative and antirheumatic. This elixir is especially useful during the subsidence of the acute symptoms, when it is desired to keep up the effect of the larger doses of the salicylates often required in the primary stage. In subacute and chronic cases the administration of the compound elixir of salicylic acid (Parke, Davis, & Co.) yields gratifying results when persistently continued. It contains forty grains of salicylic acid and four grains of potassium iodide to the fluid ounce, with cimicifuga and gelsemium. The amount of the iodide can be judiciously increased, while in obstinately chronic cases I have found the addition of from five to ten minims of the wine of calechic root very effective, especially when intestinal peristalsis is diminished and the resultant constipation has become a prominent complication. Within recent years the salicylate of methyl has come into more general use in the treatment of the pain of acute articular rheumatism.

Catrin * thinks the evidence in its favor is incontestable. As much as one ounce a day has been given. The most convenient mode of administration is by means of the gelatine globules of methyl salicylate with colchicine, originally introduced into this country from France, but now made by the well-known firm referred to above. Methyl salicylate has been used locally with marked advantage to the patient. Bandages of tarlatan soaked in the oil may be wrapped around the joint and covered by an impermeable dressing.

Arendt † has drawn attention to the value of salicylic-acid ointment in acute rheumatism. Unna, Ritter, and Ingra have shown that while salicylic acid is freely absorbed by the skin, salicylate of sodium is not so absorbed. Arendt advises the use of the following formula:

\[
\text{B: } \begin{align*}
\text{Acidi salicylici} & \quad \text{gr. ccc;} \\
\text{Oleii terebinthinae} & \quad \text{ââ } \quad \text{5ss.} \\
\text{Adipis lanana hydroderi} & \quad \text{q. s. ad } \text{5ijj.}
\end{align*}
\]

This ointment is spread on lint and applied to the joints, which are then enveloped in oiled silk and covered by a soft bandage. The usual physiological effects of the salicylates are manifested in a short time, but no gastro-intestinal complications occur. Arendt states that he has treated many cases by epidermic applications alone, and that they all have done well, although the dose is smaller than that usually given by the mouth.

In chronic rheumatism and gout improvement may not occur until after the local applications have been continued for some time. In such cases Arendt uses the following formula:

\[
\text{B: } \begin{align*}
\text{Acidi salicylici} & \quad \text{gr. ccc;} \\
\text{Spiritus vini rectificati} & \quad \text{5ijj;} \\
\text{Oleii ricini} & \quad \text{5vj.}
\end{align*}
\]

Lint is soaked in this mixture and applied to the affected joints; it is then covered with wadding and some impermeable material, like gutta-percha or oiled silk. Under the continued application of this solution the swellings and nodosities often disappear entirely.

Of other methods of treatment in vogue for several years, such as electric applications, hot air, massage, hydrotherapeutic measures, and so on, nothing need be said at this time. They have their respective uses, but, as a rule, are not available in routine practice. The general practitioner relies almost entirely upon rest, regulation of the diet, and medication to bring his cases of acute articular rheumatism to a successful issue.

Quite as important as the early administration of the proper remedies is it to take care to continue their use for some time, even after the patient seems to have completely recovered from the acute attack. In this stage the elixir of salicylates and the elixir of manaca and salicylates, previously mentioned, will prove especially serviceable. Many an otherwise promising case has relapsed and undergone a prolonged and tedious convalescence by reason of neglect of this simple precaution.

**THE TREATMENT OF FORTY-THREE CASES OF TYPHOID FEVER WITH NO DEATHS, AND WITH COMPLICATIONS IN BUT ONE CASE.**

By EDWARD C. SEUFERT, M. D.,

**ADJUNCT PROFESSOR OF HISTOLOGY AND MICROSCOPY,**

**COLLEGE OF PHYSICIANS AND SURGEONS, UNIVERSITY OF ILLINOIS, CHICAGO.**

Of late the antiseptic treatment of typhoid fever has been attacked and ridiculed by some writers. In fact, they have even gone so far as to say it does harm. Those who denounce it most strongly are chiefly those who have not given it a fair trial. This paper is written to show what results have been obtained by my rigorously following the antiseptic treatment of this fever in forty-three consecutive cases. Not one case of the entire series perished. Complications occurred in only one case, and that in a boy eight years old, of a very weak constitution; he had been continuously under my care for nearly a year previous to his attack. The result speaks for itself. What more forcible argument can be brought forward to show the efficiency of this line of treatment? I wish to lay much stress upon the necessity of strict attention to details in diet and nursing, and upon the fact that not one single grain of any coal-tar antipyretic nor one drop of alcohol was given internally.

* Jour. de méd. de Paris, June 11, 1898.
† Ann. et bull. de la Soc. de méd. d’Anvers, April, 1898.
For the sake of convenience I will consider the treatment under the following heads:

1. Rest and diet.
2. Hydrotherapy.
3. Medicines.

Rest and Diet.—As soon as the disease was suspected the patient was immediately put to bed, and under no circumstances allowed to leave it until convalescence had been established. A bellpan was used right from the beginning to prevent the patient from getting out of bed even for a few moments. When possible, patients were placed in the largest, lightest, and best-ventilated room in the house. A room with a sink was especially avoided. If the room was large enough, two beds of the same level were placed in it, so that the patient could be moved without harm from one to the other by simply pushing the empty one alongside the other, thus allowing the bed to be made and linen changed every second day with ease. Feather beds were discarded wherever possible, and a hair mattress covered with a rubber cloth and a sheet substituted. Bedsores did not develop in a single case. To prevent these, it is necessary to keep the bedclothes smoothed out, and have the back, hips, and heels frequently bathed in alcohol; also to frequently change the patient’s position in bed.

Careful nursing and diet regulation are the life-saving agents in typhoid fever. In no other disease is an appropriate liquid diet of more importance than in the one under consideration, and not only must it be liquid, but also digestible and palatable; furthermore, it should leave the least possible residue. All agree that the ideal fever food for typhoid fever is milk when it fills those requirements. If it is thoroughly acted upon by the stomach before entering the intestines there will be little chance of it mechanically irritating the ulcerated surfaces. The stools should be examined daily for undigested curds of milk, because when present they are extremely liable to cause fermentation, gas, and putrefaction, the chief factors in distention and perforation.

The milk may be given raw, boiled, or diluted with plain water, Seltzer, Apollinaris, or linewater. When diarrhea is present, it is best to give it boiled. The quantity of milk given each patient varied in quantity from one quart to three quarts in twenty-four hours, the average quantity that was well borne by adults being four to six ounces every two or three hours night and day. This quantity was usually sufficient to tide them over the height of the fever. When the milk is not being properly digested one of three things must be done: (1) the quantity must be reduced, (2) it must be predigested or peptonized, or (3) it must be entirely abandoned. On some persons in perfect health milk acts like a poison. They either become constipated, with clay-colored or white stools, or else get a diarrhea, the result of the non-digestion and fermentation of the milk. When these subjects are attacked by fever they stand it still less than in health. Kunuyss, buttermilk, or malted milk must then be given. I prefer kunuyss, if it can be obtained; one or two quarts a day can readily be digested by the weakest stomach. It is also a good diuretic. Buttermilk and malted milk may also be given as a change from time to time, especially in those cases where the prolonged use of milk has turned the patient’s stomach against it. Beef juices, beef tea, and meat extracts should not be given when the bowels are loose, because they aggravate the trouble.

When the temperature returns to normal at about the end of the fourth week the patient becomes ravenously hungry, so that it is sometimes difficult to prevent them from stealing solid food, or from obtaining it by working on the sympathy of friends. In severe cases no solid food of any kind should be allowed until the temperature has remained normal for ten days. In the milder cases, where there has been little gastric catarrh and the digestion is good, we can begin solid food two or three days earlier. It is best to begin with as light food as possible and then allow a little more each successive day. My cases were allowed a diet somewhat like the following:

First Day.—One or two cups of chicken broth and one milk toast.
Second Day.—Home-made beef tea, a cup of weak tea or coffee, and a biscuit.
Third Day.—A soft-boiled egg, cream toast, and a little scraped beef in soup.
Fourth Day.—Two or three soft-boiled eggs, rice pudding, and a baked potato.
Fifth Day.—A small piece of chicken breast, a baked apple, and one or two baked potatoes.
Sixth Day.—A small piece of tenderloin steak, mashed potatoes, bread and butter, and rice pudding.

On the seventh day the patient was allowed to select his diet from the previous six days: after that he was allowed anything he wanted except fried and fat foods. If eating caused distress, the diet was immediately reduced for a few days longer.

Thirst during typhoid fever is a very prominent symptom, and sometimes a very troublesome one. All of my cases were allowed large quantities of water that had been previously boiled and cooled. I am not in favor of giving ice, because in several cases it increased instead of decreased the intense thirst.

The free use of water favors the elimination of waste products from the system through the kidneys. Eight or ten drops of dilute phosphoric acid were occasionally added to a tumblerful of water when the patient desired it. Not only did it seem to allay thirst, but also to aid digestion.

Hydrotherapy.—Systematic cold sponging was begun in each case as soon as the diagnosis was suspected. Equal parts of water and alcohol were used in every case. When the temperature went above 102.5° F. the
patient was thoroughly sponged every two hours; otherwise it was done every three or four hours, as necessity required. The limbs should be sponged and dried in succession, and then the trunk; each sponging should take up fifteen minutes' time. An ice-bag to the head greatly increases the efficacy of the sponging. When the temperature could not be sufficiently controlled by sponging, a wet pack was used. The patient was wrapped in a folded sheet which had been wrung out in cold water and which was afterward kept constantly wet by the addition of more water. For the intense headache of the first week of the disease nothing has given as much satisfaction in my experience as the ice-cap or ice-bag.

There is no doubt that antipyretics by reducing the temperature reduce the patient's strength and resistance, and should therefore never be given.

The Brand method of cold baths was not tried on any case in this series; it is very impracticable in private practice, and is strenuously objected to by both the patient and his relatives. And why should we employ it as long as systematic cold sponging accomplishes the same good?

Cold sponging, like the cold bath, undoubtedly strengthens the heart, keeps the mind clear, lessens nervous symptoms, induces sleep, and diminishes muscular twitches and tremors.

The mouth should be kept scrupulously clean. Nothing is so liable to coat the tongue as milk. After taking a glass of milk the mouth ought to be washed out with a saturated solution of boric acid. When this is faithfully done we seldom see those dry, brown, leathery, and fissured tongues called "typhoid tongues." By keeping the mouth clean we seldom find cases of abscess in the parotid or middle ear.

**Medicinal Treatment.**—The medicinal treatment employed can be expressed by the two terms **elimination and intestinal antiseptics.** As soon as typhoid fever was suspected calomel was administered in one-grain doses every two hours for the first twenty-four or thirty hours. The first prescription was as follows:

| R | Hydrarg. chlor. mit. | grs. xx |
| Sod. bicarbon. | grs. xl |
| Sacch. lact. | 3ss |
| M. et f. in chart. No. xx |

Sig.: One powder every two hours.

This was given whether the attack was ushered in with diarrhea or constipation. It almost invariably checked diarrhea and vomiting when present. In this way much poisonous and fermenting material in the intestines was eliminated from the system. After the patient's alimentary tract had been well cleared the administration of intestinal antiseptics was begun. Of these, salol, naphthalin, and carbonate of guaiacol have proved of the most benefit in the cases under my observation. Each was given for one week, beginning with salol and ending with guaiacol. As soon as the calomel treatment was stopped, salol in five-grain doses was administered every two hours for the next week. Salol is composed of sixty parts of salicylic acid and forty parts of carbolic acid; it begins to split up into its original components as soon as it passes into the intestine. It should be given in capsules or gelatin-coated pills. The salol is followed by naphthalin in five-grain doses in capsules every three hours, and is also continued for a week. At the end of this time carbonate of guaiacol is prescribed in capsules in two-and-a-half-grain doses, to be given every three hours until convalescence. No other internal medication was used during the course of the fever unless complications set in.

**Constipation** after the first week was relieved by small doses of Rubinetar water, two ounces every three hours until effective. This saline laxative water does not excite excessive peristaltic action. When bronchitis was present at the beginning of the disease malto-verbine was given in doses of one teaspoonful every two hours until relieved. Occasionally a ten-grain dose of sulphonal was ordered to procure a little quiet sleep. Headache, no matter how intense, was combated by the ice-bag in every case. Alcoholic stimulants were not given in a single instance. Meteorism and diarrhea, which occurred in only six cases in the third week, were easily controlled by oil of turpentine and deodorized tincture of opium in an emulsion, in the proportion of two minims of the former to three minims of the latter to each dose every three hours. A right-sided pneumonia, chorea, pericarditis, and endocarditis were complications which all occurred in a boy eight years old. Ice-bags were placed over his right side and over the precordia. Arsenic was given internally in the form of Fowler's solution, three drops every four hours in water. Strychnine was also administered in full doses. Professor Quine saw this case in consultation and verified my diagnosis. The chorea disappeared shortly after convalescence. This was the only case in the entire series that presented any complications. As soon as convalescence set in intestinal antiseptics were gradually supplanted by tonics. Of these, maltine and its compounds were most freely used because most agreeable to the weakened stomach. If the digestion was very weak, maltine with wine of peptic was given in tablespoonful doses after each feeding. If constipation was present, maltine with cascara sagrada was administered in teaspoonful doses three or four times a day. As a final all-round tonic, maltine with iron, quinine, and strychnine was prescribed in teaspoonful doses four times a day. Maltine seems to be especially suitable in typhoid fever, as it supplies not only nutriment, but assists the functions of the digestive organs on account of its richness in diastase. It does not, as some claim, lose its properties when it comes in contact with the acids of the stomach, but, on the contrary, they stimulate diastatic action, at any rate in the earlier stages of digestion.
Remarks.—The average duration of the fever was twenty-one days. In infants typhoid fever runs a much shorter course, two being included in my series, one thirteen months old, the other fifteen months old; the former was well in fourteen days, the latter in sixteen days. In infants it usually begins abruptly with nervous symptoms, cerebral in character, as a rule intensified by high temperature. There is splenic enlargement in every case with the typical eruption on the abdomen in half the cases. There is great prostration, dry tongue, thirst, and pallor. Their blood responds to Widal’s test equally as well as that of adults. It is unusual for an infant to die of typhoid fever. The intestinal lesions are never severe, the ulcers being very superficial. The reason for this difference in the character of the lesions, the reason for the ulcers being less marked and less deep, has been stated by some to be the unirritating diet usually taken by the very young. Does not this look reasonable, and does not this condition of affairs in the intestinal tract offer an explanation of the disease and the lower death-rate?

The longest case in the series lasted nine weeks. Seventy-five per cent. of the cases occurred during the ages of eight and thirty, as shown by the following table:

<table>
<thead>
<tr>
<th>Age Group</th>
<th>Number of Cases</th>
</tr>
</thead>
<tbody>
<tr>
<td>Between one and two</td>
<td>2 cases</td>
</tr>
<tr>
<td>two and eight years</td>
<td>4</td>
</tr>
<tr>
<td>eight and twenty years</td>
<td>18</td>
</tr>
<tr>
<td>twenty and thirty years</td>
<td>13</td>
</tr>
<tr>
<td>thirty and forty years</td>
<td>5</td>
</tr>
<tr>
<td>forty and fifty years</td>
<td>1 case</td>
</tr>
</tbody>
</table>

Out of the forty-three cases, twenty-nine were females and fourteen were males. The temperature reached 105.5° F. in three cases. The lowest observed temperature occurring as the maximum in any case was 101.8° F. High temperature was seldom present longer than two days. The following is a tabulation of the frequency of some of the prominent symptoms that characterize typhoid fever:

**Abdomen:**
- Rose spots: 35 cases
- Tenderness and gurgling in right iliac fossa: 43 cases
- Spleen enlarged: 38 cases
- Spleen markedly enlarged: 5 cases
- Typhoid test: positive in 32 cases
- diarrhoea: 30 cases
- Constipation: 13 cases

**Tongue:**
- Dry, coated, red at tip and margins: 30 cases
- Coated, white fur: 10 cases
- Dry, brown, and fissured: 2 cases
- Sordes, lips and teeth: 1 case

**Epistaxis:**
- Mild: 34 cases
- Severe: 3 cases
- Absent: 6 cases

**Bronchitis:** 30 cases

**Delirium:**
- Mild: 3 cases

Widal’s reaction was obtained in the last twenty-three consecutive cases; those occurring before that time had their urine subjected to Ehrlich’s diazo-reaction, which proved a valuable aid to diagnosis in doubtful cases, although not as positive a means as the blood-serum test. A numerical corpuscular examination of the blood in ten cases showed nothing further than a slight decrease in both red and white cells, more so of the latter. The pulse rate was always slow and out of proportion to the temperature—for example, the pulse may be seventy-five or eighty and the temperature 104.5° F. The pulse is very frequently dicrotic, especially at the beginning of the disease. When pneumonia occurs as a complication the pulse rate immediately runs up to one hundred and ten or one hundred and twenty or higher. The same is true of other conditions complicating typhoid fever.

---

**SOME REMARKS ON THE USE OF SUPRARENAL CAPSULE IN THE NOSE AND THROAT.**

By J. CLARENCE SHARP, M.D.,
CONSULTING LARYNGOLOGIST TO THE HARBOR HOSPITAL; ASSISTANT SURGEON TO THE NOSE AND THROAT DEPARTMENT, BELLEVUE DISPENSARY;
CLASS READER TO THE NOSE AND THROAT CLINIC, PREBENITARY HOSPITAL.

I was very much interested in the article which appeared in an October number of the Medical Record, by Dr. W. H. Bates, upon the use of suprarenal gland.

So many of these new preparations are put forward every year with promises which are never fulfilled that we become very skeptical and hesitate to make use of them.

For a long time we have been on the lookout for some astringent besides cocaine that will contract the nasal mucous membrane without any danger or ill effect to the patient, and at the same time can be given into the hands of the patient for use at home. This I think we have found in the suprarenal capsule.

The following are the conditions in which the aqueous extract will be found beneficial:

**Nose.**—In making an examination of the nose, when the turbinates are very much hypertrophied and the mucous membrane is not too sensitive, cocaine can be dispensed with and the aqueous extract of the capsule applied locally. In this case it is best to apply the solution to the anterior portion and wait about two minutes. By this time the mucous membrane is so contracted that the solution can then be applied to the middle and posterior portion. When the parts are under the full effects of the solution the inferior and posterior portions will appear white. In very large hypertrophies of the inferior turbinates, when the mucous membrane is in folds and of a grayish color, cocaine
will reduce the hypertrophy very little, but if the solution of suprarenal capsule is applied the reduction is plainly noticed. It is in this condition of the inferior turbinates, which we call a true hypertrophy, that we are more likely to have both a primary and secondary hemorrhage after operation. Now I can operate and not have enough bleeding to soil a large napkin.

**Sphenoid.**—In sphenoid operations, no matter how extensive, the hemorrhage is very much reduced.

**Vault of the Pharynx.**—I have used it to reduce the congestion, especially after a purulent exudate of the vault, with very good results.

**Pharynx.**—The follicles often become congested behind the posterior pillars. The application of the solution will relieve the congestion, reduce the inflammation, and Blanch the follicles.

I always apply the solution to the stump after an amygadalotomy.

**Acute Amygdalitis.**—The application of the solution applied directly to the tonsils will relieve the congestion and soreness.

**Larynx.**—In subacute laryngitis the cords will be seen to whiten and the congestion become very much reduced after spraying with the aqueous extract. This will be of great benefit to singers, especially as it can be repeated without any danger whatever.

**Cauterization of Inferior Turbinates.**—It binds down the tissue longer when used with cocaine, and lessens the congestion of the turbinates after the use of the caustic.

**Hay Fever.**—I hope we have found something that will give the poor sufferers from this disease some relief. At least we can feel assured that it will contract the mucous membrane as much as cocaine without the danger and depressing effect of the latter.

In all acute inflammation of the nasal mucous membrane I like the effect very much better than that of cocaine. I have found that the best result is to be had when the solution is applied directly to the mucous membrane and not sprayed.

After operations always clean off the surface and again apply the solution, which prevents the oozing until the crust has time to form.

I use a ten-per-cent. aqueous extract and make up a small quantity at a time, as it decomposes very quickly. I have been using the solution every day for nearly a year, and am greatly charmed with the results.

**Therapeutical Notes.**

**Extract of Whortleberry in the Treatment of Eczema.**—Daxenberger (Centralblatt für Kinderheilkunde, 1898, iii, 439; American Journal of the Medical Sciences, August) speaks very favorably of this drug in various forms of eczema, especially in children; also in the nycotic forms in smaller ulcerations of the skin and mucous membranes, rhagades, etc. The extract, of the consistence of syrup, is applied by means of a brush after the surface has been cleansed and dried. Over this a dusting powder may be sprinkled. Drying takes place rapidly, and the pellicle adheres so tightly that other dressing is unnecessary. By this means eczema was often cured in one to two days.

**A Tooth Wash for Children.**—The Gazette hebdomadaire de médecine et de chirurgie for May 7th credits Carron de la Carrière with the following formula:

- R Thymol ................. 100 parts;
- Benzonic acid .................. 10 “
- Oil of mint .................. 5 “
- Oil of star-anise ......... 4 “
- Tincture of cochineal ........... 12 “
- Alcohol .................. 460 “

M. Add to a glass of water enough of the mixture to make it cloudy, and cleanse the teeth every morning, in children two years old or more, with a wad of cotton wet with the water thus aromatized.

**A Collutory for Factor of the Mouth.**—The Reforma medica for June 3d gives the following formula:

- R Camphor ................. 5 parts;
- Salicylic acid, 1 each ........ 10 “
- Oil of anise, 1 each........ 20 “
- Powdered benzoin, 1 each... 20 “
- Calcium hypoehlorite ......... 120 “
- Glycerin .................. 200 “
- Alcohol .................. 300 “

M. Keep in a colored bottle. A coffee-spoonful, in a glass of water, to be used as a mouth wash.

**The Vomiting of Pregnancy.**—Dr. John P. Dow (Massachusetts Medical Journal, August) says that in mild cases of the vomiting of pregnancy, when medication is not desirable or feasible, he is very fond of following an old German custom. He advises the patient to take a small cup of strong coffee upon waking in the morning—best without sugar and cream—then to remain quietly in bed for an hour before getting up.

**Condurango in the Treatment of Dyspepsia.**—The Gazetta degli ospedali e delle cliniche for June 6th gives the following formula. The first is Friedreich’s, and the other is Krauss’s.

1. R Condurango bark .......... 15 parts;
   Water .................. 300 “

   Macerate for twelve hours and boil down to a hundred and fifty parts.

   A soup spoonful to be taken three times a day.

2. R Powdered condurango bark 225 grains;
   Hydrochloric acid ........ 15 drops;
   Syrup of bitter-orange peel 2,250 grains.

M. S.: A soup spoonful every two hours.

**The Use of Salol in Acute Amygadalitis.**—The Progrès médical for June 17th ascribes the following to Carron de la Carrière:

- R Salol .................. 60 grains;
   Oil of sweetalmonds, 1 each, 120 “
   Gum arabic, 1 each ......... 120 “
   Syrup .................. 750 “
   Distilled water ........... 1,950 “
   Essence of mint ........... q. s.

M. A soup spoonful every two hours.
LOCAL ANÆSTHESIA BY COCAINIZATION OF THE SPINAL CORD.

Beginning about fifteen years ago, Dr. J. Leonard Corning, of New York, has given a great deal of attention to the employment of cocaine for the purpose of producing local anesthesia under conditions that, except for his remarkably ingenious devices, would in all probability have prevented the establishment of such an anesthesia. More than that, he early entertained the idea of anaesthetizing distant parts by cocainizing those portions of the spinal cord from which they derived their sensory innervation, and he proceeded to test the notion experimentally. For example, as was related by Dr. Corning in the New York Medical Journal for October 31, 1885, the fact that numerous small veins, running between the spinous processes of the vertebrae, entered the spinal canal and joined the larger veins of the internal spinal plexus was taken advantage of by him to anaesthetize more or less of the substance of the spinal cord, and consequently parts of the lower limbs that derived their sensory nerves from those points in the cord, by injecting cocaine between the spinous processes. He did this both upon the dog and upon the human subject, and in each the soundness of his reasoning was clearly shown by the production of more or less profound anesthesia of the lower limbs. In subsequent publications Dr. Corning described his further investigations of the subject of mediate anesthesia, as it might be termed, and notably his experiments in cocainizing the cauda equina.

Whatever may prove to be the practical value of these devices of Dr. Corning's, he is undoubtedly entitled to the credit of having thought them out and demonstrated their feasibility. But, like many other discoveries, these have been overlooked, and recently a great deal of credit has been given to Beer for essentially identical devices described by him in the Deutsche Zeitschrift für Chirurgie for April, 1899. We would not in the least detract from Beer's title to originality. In such matters originality is quite a different thing from priority, and he who invents something, not knowing of its having already been invented, shows a degree of ingenuity fully equal to that of the prior inventor, but with that amount of credit he should rest content. Dr. Corning must be credited, not only with the originality that is conceded to Beer, but with priority in addition, and priority is not insignificant, for it betokens mental alertness. We are glad to see that our esteemed contemporary the Medical Record, in whose own columns some of Dr. Corning's experiments were described in 1888, recognizes in its issue for August 5th that gentleman's title to be acknowledged as having been first in the field in the matter of cocainization of the spinal cord.

THE NEEDS OF THE ARMY MEDICAL DEPARTMENT IN PEACE AND WAR.

Surgeon-Lieutenant-Colonel Wrench, in the British Medical Journal for July 23d, concludes a most interesting and graphic picture of the Crimean War, in which he served as a regimental surgeon, with some remarks which have for us a special bearing on recent events. He says: "I shall probably be expected to make some remarks on the breakdown of the medical arrangements. From what I have already described you will, I think, see that it was the system, and not the men, that failed. The medical department was, like every other in the army of that date, quite unprepared for a great and prolonged war, hampered by red tape, and denied all independence of action. Miss Nightingale justly received great praise for the improvement she effected in the larger hospitals. Had the surgeons been given her power to obtain what they required regardless of cost, much of the misery and mortality in the hospitals would have been averted before her arrival. The old regimental system of hospitals and medical officers was, and probably is, the best in time of peace, but it must break down in time of war. It is clearly better to practise in garrison what will have to be carried out in the field than, as Abraham Lincoln remarked, 'have to swap horses when fording the stream.' Wars always have been and always will be cruel. It is, however, the pride of our profession that, while sharing the fatigues and dangers of the campaign, our sole duty will always be the protection of the soldier from what after all is his most deadly enemy—disease—and the alleviation of the sufferings of the wounded. The Crimean campaign taught a lesson which I trust will never be forgotten by the nation, that unless the medical department of the army is made efficient, and supplied with its proper complement of officers and ambulance during peace, it can not be expected to do its duty efficiently during war."

The regimental system of medical aid always has
been, and inevitably must be, a failure on the field of battle, however satisfactory it may be in camps and quarters in time of peace. Much of the difficulty in our late war arose from the opposition on the part of regimental surgeons to being abruptly changed from a system with which they were acquainted to one with which they were not, and the time requisite to render them familiar with the details of their new routine. As Colonel Wrench says, "it is clearly better to practise in garrison what will have to be carried out in the field." To have adequate medical accommodation for all the casualties and disease that can possibly happen in each unit would be cumbersome, and expensive beyond all reason; while, if the accommodation in each unit is based, as it must be, upon a consideration of averages, it will constantly occur that the medical arrangements of one unit will be broken down by excessive demands upon them, while others are practically kept in idleness. Mobility, not fixedness, is the requisite, and that can only be attained by a properly organized and independent department.

UNIFORMITY OF STATE LICENSE REQUIREMENTS.

We take it that nobody questions the desirability of uniform requirements for State licenses to practise medicine, a state of things in which a person who had received a license in any State would be entitled ipso facto to the license in any other State. But this, we fear, is at present impracticable, so diverse are the requirements in many of the States. It does, however, seem feasible for certain States having practically identical requirements to establish reciprocity, at least in a tentative way, and this has already been advocated by men influential in the profession. To the Wayne County (Michigan) Medical Society we must give the credit of having made what is, so far as we know, the first tangible move in the matter. At a meeting held on June 22d the society appointed a committee of five "to investigate the best way of furthering the idea of a national health board and to consider the steps to be taken which, in time, may lead to a uniformity of the requirements for the license of practising medicine throughout the United States." The committee consists of Dr. George G. Gordon (president), Dr. E. B. Smith, Dr. F. D. Summers, Dr. E. H. Troy, and Dr. E. Amberg (secretary).

We do not know what these gentlemen have accomplished in regard to furthering the idea of a national health board; they seem to have postponed that part of their task, very wisely, we think, and set themselves earnestly to work on the reciprocity scheme. They have sent to the authorities of each State and Territory a circular of inquiry dated July 21st. In this circular they ask when a medical law was established in the State or Territory; what amendments have been made since 1898 and when they were made; whether other amendments are expected, and what their character is; what, if any, State, American, or foreign diplomas are acknowledged; whether the plan of entering into reciprocity with other States having practically the same requirements would be considered favorably; whether the officials addressed would join in efforts to work out a memorandum to be presented to the legislative bodies of the different States with a view to framing a bill on the subject; and whether the authorities addressed have any suggestions to make.

These questions are readily intelligible, to the point, and susceptible of brief and definite answers. We trust that the various officials to whom the circular has been sent will realize the importance of the scheme of approach to uniformity, and give the gentlemen of the committee full information on all the points covered by their inquiries. We hope also that the steps taken by the Wayne County Medical Society will speedily lead to as great a degree of inter-State reciprocity as is at present practicable, and ultimately to uniformity of requirements throughout the United States.

CHIROPODY IN THE ARMY.

One of the most essential conditions of an effective fighting force is the possession of good marching powers. The grosser causes which impair marching ability, such as varicose veins, etc., are, of course, attended to in the physical examination on enlisting; and should they develop subsequently to enlistment, the soldier comes under the care of the medical department. But there are minor troubles in the feet which may seriously impair the soldier's efficiency in this particular. The British military authorities have taken a very practical step toward obviating these by causing the non-commissioned officers of the army medical corps to be trained in the art of chiropody. This is a point which would well repay imitation.

TUBERCULOSIS AS A CONTAGIOUS DISEASE.

At the Medical Society of Brussels, M. Tiberghien (Gazette hebdomadaire de médecine et de chirurgie, July 29th) recently related the following case: A woman, always previously in good health, came under his care. There was no suspicion of tuberculosis in her parents. She had recently come to dwell in a house where many tuberculous persons lived, one of whom had died, and her clothes, without being disinfected, had been distributed. The woman in question received a dress, which she wore daily. From this period dated the first symptoms of her illness, vague symptoms at-
taching to the pleura and peritonæum, with some aug-
mentation of the size of the liver and spleen. These
symptoms disappeared after a short time, and the gen-
eral condition markedly improved, but shortly, conse-
quent on a contusion, a tuberculous abscess developed
in the left elbow, and was opened and curated. A fis-
tula with signs of peritonitis persisted. Subsequently,
very pronounced tuberculous signs appeared in some
of the other bones, notably a lumbar vertebra, the gen-
eral condition, however, remaining satisfactory. Final-
ly, acute symptoms developed in the lungs, and the
patient died within six months. This would appear to
be an unusually convincing instance of tuberculous con-
tagion.

THE EFFECTS OF ALCOHOLISM ON OFFSPRING.

M. Barbier, according to the Journal des praticiens for July 13th, recently related to the Société médicale des hôpitaux the history of a Parisian family the issue of an alcoholic father and a temperate mother. The children had been conceived while the father was in a state of inebriety. Of four living children, none was normal. Some showed arrest of development of one or more fingers, others were rhachitic, or did not develop teeth. There were no stigmata of syphilis. The investigations of M. Péré into the influence of alco-
holism on the development of the embryo and in the production of monstrosities would appear to receive some support from M. Barbier’s cases.

AN "EPIDEMIC" OF INFANTILE PARALYSIS.

The almost simultaneous occurrence of a number of cases of paralysis among children in Doughkeepsie and in a few other places in the State of New York, and continued reports of fresh cases, justify to some extent, perhaps, the popular idea of an epidemic. The disease is generally set down as a poliomyelitis of an acute form, but we think sufficient accurate observations have not yet been made to justify a positive statement on this point. The outbreak appears to be subsiding.

DISCONTENT IN THE BRITISH INDIAN MEDICAL SERVICE.

A medical service should always be unarmmaned by the interference of line officers; otherwise, there will be inefficiency as well as discontent. An example is cited in the Indian Medical Record for June 28th. No administrative power is given to the medical officers in the plague operations, and in one district a certain captain “considered it within his right to determine who should, and who should not, be discharged from hospital.” Many such instances of interference are stated to have occurred, and in consequence there is much discontent among the medical officers.

CHRONIC SUPPURATIVE ACRODERMATITIS.

Prolonged suppuration of the skin must, we pre-
sume, be counted among the rarities of dermatology, if we except the cases of weeping eczema in which the discharge is more or less purulent. At a recent meet-
ing of the Société de dermatologie et de syphiligraphie (Gazette hebdomadaire de médecine et de chirurgie, June 29th) M. Hallopcau showed a patient whose hands had been the seat of purulent dermatitis for eighteen years, and remarked that he had lately seen a case in which the greater part of the whole cutaneous surface was affected by extension from the hand. He attrib-
utes the trouble to pyogenic microbes which penetrate in consequence of traumatism, and says that fatal purul-
ent infection may take place.

THE CAUSTIC ACTION OF GARLIC JUICE.

Domestic remedies are not always harmless. An example of this fact was recently brought to the attention of the Paris Medico-chirurgical Society by M. Gillet (Presse médicale, July 8th). The case was that of a boy whose thumb showed severe ulceration resulting from the application of garlic continuously for eight hours for the purpose of curing a wart. M. Vigier remarked that the caustic agent, allyl sulphocyanide, did not preexist in the plant, but was developed on con-
tact with moisture.

ILEMATO-HYDRO-NEPHRO-URETEROSIS.

Under this name, Dr. John H. Summers, Jr., of Omaha (Medical Record, July 29th), gives an exceed-
ingly interesting account of a case in which the kidney and ureter were distended with a bloody and watery liquid, forming a large cyst which he removed by an extraperitoneal operation with complete success. It seems as if a shorter term, and yet one sufficiently ex-
pressive, might be applied to such a cyst.

TUMORS OF THE NIPPLE.

Remembering how tender and vulnerable a struc-
ture the nipple is, we may well wonder that it is not of
ten the seat of neoplasms. With Paget’s disease we are, indeed, tolerably familiar, but it is not often that we encounter real tumors of the nipple. Dr. O. Eh
hrhard, of Königsberg (Deutsche Zeitschrift für kli-
nische Chirurgie, 1, 3, 4; Centrallblatt für Gynäkologie, July 22d), records two examples. One was polypoid in form and of the nature of elephantiasis. The other was a carcinomatous nodule no larger than a pea, but it had already infected one of the axillary glands.

THE COLD-BATH TREATMENT IN DELIRIUM TREMENS.

In medicine, as well as in political affairs, history re-
peats itself. A long article on the treatment of delirium tremens with cold baths appears in the Presse médicale for July 8th. The method is not quite a nov-
elty in France, although it seems to have fallen into disuse in that country. The author, M. Maurice Le-
tulle, refers to a previous communication of his, pub-
lished in the same journal in 1886, and cites authors of various periods as having favored the treatment. It has undoubtedly proved very efficacious in some se-
vere cases. It was in vogue here in New York thirty years ago, and its chief promoter, if we remember aright, was Dr. Lewis A. Sayre.

GRACE HOSPITAL, TORONTO.

Our brethren in Toronto are to be congratulated on the transformation of Grace Homeopathic Hospital into plain Grace Hospital. We learn from the August number of the Canadian Journal of Medicine and Sur-
gery that there is still to be a homoeopathic staff, but
also that there is to be what the secretary, in his official announcement, terms "an allopathic" staff. We hope that in time this distinction, too, will fade away.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the week ending August 5, 1899:

<table>
<thead>
<tr>

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 29 to August 5, 1899:

BALCH, Lewis, Major and Surgeon, United States Volunteers, is assigned to station in Matanzas.

BANTA, William P., Acting Assistant Surgeon, United States Army, will proceed to San Fernando, Philippine Islands, for duty in the Second Division Field Hospital.

BURNS, Robert, Acting Assistant Surgeon, United States Army, will proceed to Fort Ethan Allen, Vermont, and report to the commanding officer, Third United States Cavalry, for duty, to accompany that regiment to Manila.

CIMELICK, Joseph F., Acting Assistant Surgeon, United States Army, will report for duty at the United States General Hospital at the Presidio, San Francisco.

DEAN, Elmer A., First Lieutenant and Assistant Surgeon, is assigned to duty at the United States General Hospital at the Presidio, San Francisco.

GARDNER, Edwin F., Major and Surgeon, United States Army. The leave granted him is extended seven days.

HALL, William R., Major and Surgeon, United States Army, will proceed to New York, and on completion of the duty assigned him will sail as a passenger on the United States hospital ship Missouri, en route to Manila, and on arrival will report to the commanding general.

KEEPER, Frank R., Captain and Assistant Surgeon, United States Army, is relieved from duty with the board of officers appointed by Par. 2, S. O. 130, c. s., these headquarters, and CALVERT, William J., First Lieutenant and Assistant Surgeon, United States Army, is appointed in his stead.

MAZZURI, Paul, Acting Assistant Surgeon, United States Army, is assigned to the Department of Matanzas and Santa Clara, and will proceed to Matanzas for duty.

NORMAN, Seaton, Acting Assistant Surgeon, United States Army, having relinquished the unexpired portion of his leave, will proceed to Fort Monroe, Virginia, for temporary duty.

VON CLossman, August, Acting Assistant Surgeon, United States Army, and two privates of the hospital corps, will accompany Troop K, Third Cavalry, to Seattle, Washington, and return to Jefferson Barracks, Missouri.

WEAVER, Frederick C., Acting Assistant Surgeon. United States Army, is assigned to duty at the camp of recruits, at the Presidio, San Francisco.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Week ending August 5, 1899:

CRAWFORD, C. A., Assistant Surgeon. Detached from the Wabash and ordered to the Massachusetts.

ELIOTT, M. S., Assistant Surgeon. Detached from the marine examining board and ordered to temporary duty at the marine recruiting rendezvous, New York, during the leave of absence of BOGERT, E. S., Passed Assistant Surgeon; upon completion of this duty, he is directed to await orders.

GROW, E. J., Assistant Surgeon. Detached from the Massachusetts and ordered to the New Orleans.
HERNDON, C. G., Surgeon. Ordered to the Museum of Hygiene for temporary duty.

PLEADWELL, F. L., Assistant Surgeon. Detached from the Nashville and ordered to the Bureau of Medicine and Surgery.

ROSENBLEUTH, J. C., Passed Assistant Surgeon. Detached from the Vermont and ordered to the Nashville.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending August 3, 1899:

WASDIN, EUGENE, Surgeon. To proceed to National Soldiers' Home, Virginia, for special temporary duty. July 29, 1899.

MAGRUDER, G. M., Passed Assistant Surgeon. To proceed to Hampton, Virginia, for special temporary duty, reporting at the bureau en route. So much of bureau order of July 31, 1899, directing Passed Assistant Surgeon Magruder to proceed to Hampton, Virginia, revoked, and directed to proceed to Richmond and Newport News, Virginia, for special temporary duty.

WERTENBAKER, C. P., Passed Assistant Surgeon. To proceed to Hampton, Virginia, and report to Surgeon J. H. White for special temporary duty.

SMITH, A. C., Passed Assistant Surgeon. Leave of absence granted by bureau letter of June 29, 1899, revoked, and directed to rejoyn station at Norfolk, Virginia.

STIMPSON, W. G., Passed Assistant Surgeon. To proceed to Fort Monroe, Virginia, for special temporary duty, reporting at bureau en route. So much of bureau order of July 31, 1899, directing Passed Assistant Surgeon Stimpson to proceed to Fort Monroe, Virginia, revoked, and directed to proceed to Newport News, Virginia, and report by wire to Surgeon J. H. White, Hampton, Virginia, for orders.

BLUE, RUPERT, Passed Assistant Surgeon. To proceed to Columbus City, Washington, for special temporary duty.

VON EZONE, R. H., Assistant Surgeon. To report to Surgeon J. H. White, Hampton, Virginia, for special temporary duty.

FRICKS, L. D., Assistant Surgeon. Relieved from duty at the South Atlantic Quarantine Station and directed to proceed to Hampton, Virginia, and report by wire for further orders.

THORNBERRY, F. J., Assistant Surgeon. To proceed to Cleveland, Ohio, for temporary duty. Bureau order of July 28, 1899, directing Assistant Surgeon Thornbury to proceed to Cleveland, Ohio, for temporary duty revoked. Relieved from duty at New York and directed to proceed to Baltimore, Maryland, and report to the commanding officer for duty and assignment to quarters.

BEAN, L. C., Acting Assistant Surgeon. Granted leave of absence for fourteen days from August 4, 1899.

GIBSON, L. P., Acting Assistant Surgeon. Granted leave of absence for ten days.

MCGINNIS, R. H., Acting Assistant Surgeon. Granted leave of absence for three weeks from August 7, 1899.

MARTIN, H. M.D., Acting Assistant Surgeon. Granted leave of absence for thirty days on account of sickness.

SMITH, A. W., Acting Assistant Surgeon. To proceed to Fort Monroe, Virginia, and report to Surgeon W. J. PETTUS for special temporary duty.

RODMAN, JOHN C., Sanitary Inspector. Granted leave of absence for four days.

KOLL, W. W., Hospital Steward. To proceed to Hampton, Virginia, and report to Surgeon J. H. White for special temporary duty.

PECK, F. H., Hospital Steward. To proceed to Fort Monroe, Virginia, and report to Surgeon J. W. PETTUS for special temporary duty.

DAVIS, H. E., Hospital Steward. To proceed to Baltimore, Maryland, and report to commanding officer for temporary duty.

OLSEN, E. T., Temporary Hospital Steward. Relieved from duty at Chicago, Illinois, and directed to proceed to Wilmington, North Carolina, and report to commanding officer for duty and assignment to quarters.

Resignation.

DE KRAFFT, S. C., Acting Assistant Surgeon. Resignation accepted, to take effect July 15, 1899.

Appointments.

GOLDSBOROUGH, B. W., of Maryland, appointed acting assistant surgeon, United States Marine-Hospital Service, for duty at Cambridge, Maryland.

OLSEN, EGIL T., Temporary Junior Hospital Steward, appointed junior hospital steward from May 29, 1899.

Change of Address.—Dr. Mary Scott, to 400 East Genesee Street, Syracuse, New York.

Births, Marriages, and Deaths.

__Married.__

FLYNN—MACDONALD.—In Providence, Rhode Island, on Wednesday, August 2d, Dr. Henry Sherman Flynn and Miss Jessie Margaret MacDonald.

LE SAGE—BOUVIER.—In Montreal, Canada, on Thursday, August 3d, Dr. Joseph A. Le Sage and Miss Lora Bouvier.

LONG—WARMAN.—In Plainfield, New Jersey, on Wednesday, August 2d, Dr. Eli Long, Jr., of New York, and Miss Bertha F. Warman.

LUSK—MONAHAN.—In New York, on Monday, August 7th, Dr. Obed L. Lusk and Miss Margaret Graham Monahan.

__Died.__

BRIXTON.—In Atlantic City, New Jersey, on Monday, July 31st, Dr. Daniel Garrison Brixton, of Philadelphia, in the sixty-third year of his age.

GILBERT.—In Quincy, Massachusetts, on Friday, August 4th, Dr. John H. Gilbert, in the sixty-seventh year of his age.
SPECIAL ARTICLES.

THE LAW IN ITS RELATIONS TO PHYSICIANS

BY ARTHUR N. TAYLOR, LL.B.

CIVIL MALPRACTICE, INCLUDING GENERAL LIABILITY OF PHYSICIAN TO PATIENT.

(Continued from page 208.)

That Services were Gratuitous is no Defense.—In examining the contract of the physician as implied from his relations to his patients it was observed that the fact that his services were rendered without compensation or reward did not alter the character of his obligations to his patient or relieve him from liability for the breach of such obligation. This was not always considered the law, nor is it now the law as applied to the ordinary relations and affairs of life. Under the common law the degrees of negligence are usually characterized as slight, ordinary, or gross, and the particular degree of negligence which the defendant must have been shown to be guilty of in order to fix liability upon him varied in the inverse ratio of his compensation. If he was well paid for performing certain services he could be guilty of slight negligence only at his peril; if, on the other hand, he received no compensation, nothing short of gross negligence would be considered culpable; but where the compensation was the usual and ordinary amount liability would attach for damages suffered from ordinary negligence.

This was the rule which the courts applied at an early date in fixing the liability of physicians for professional errors. The courts very soon, however, detected the pernicious effects which might be reasonably expected to follow the application of such a rule of liability to the practice of a learned profession like that of medicine, which deals not only with the health and, in a great measure, the happiness of the people, but their very lives; and, accordingly, by a line of well-considered decisions they have held the physician strictly to the prescribed requirements of professional ability and care, whether his services are paid for or gratuitous. The reason and the necessity for this rule are

clearly and urgently expressed in an instruction delivered by Justice Pryor, from which an extended quotation is made in chapter ii of this work.

The application of the rule of liability for error or neglect in medical treatment, whether compensation is made or not, is only applicable, it must be remembered, in cases where the defendant holds himself out as a physician and surgeon. If one not professing to be a qualified physician, and the patient not understanding him to be one, undertakes to render medical services without compensation, such services, though improperly rendered, will be considered by the court as a mere kindly or neighborly office and incapable of supporting an action for damages.

Liability of Other than Qualified Physicians for Malpractice.—From the foregoing paragraph it must not be inferred that one who, in fact, is not a qualified physician, but who holds himself out as such, may escape any of the liability which attaches to a regular physician for improper treatment. The mere fact that one solicits patients, representing himself as competent to treat them, brings with it all of the penalties to which the regular physician is liable. Justice Lyon, in the case of Nelson vs. Harrington, said the rule is elementary that a physician or surgeon, or one who holds himself out as such, whether duly licensed or not, when he accepts an employment to treat a patient professionally, must exercise such reasonable care and skill in that behalf as are usually possessed and exercised by physicians or surgeons in good standing, of the same system or school of practice, in the vicinity or locality of his practice, having due regard for the advanced state of medical or surgical science at that time. In this case the defendant was a charlroent physician or spiritualist, who professed to have no medical education or training; yet the mere fact that he held himself out as being possessed of ability to treat patients through the occult aid vouchsafed him, and accepted the duties and undertook the functions of a physician, rendered him amenable to the same law governing their liabilities.

Whether or not in such cases the defendant does hold himself out as a physician is usually a question of fact for the jury to decide from the evidence, and it is often a question requiring nice discrimination. In an early Wisconsin case the evidence adduced at the trial to show that the defendant held himself out as a physician was that he was called as a physician in the first instance; that he attended the case and consulted with a certain doctor; and that he was called doctor during his attendance. The evidence showed that he attended as surgeon seven weeks, assuming the whole direction and treatment of the injured limb, and went into consultation with other physicians and surgeons. Regarding this evidence the supreme court said: “These facts, though not perhaps direct proof of his holding himself out as a physician and surgeon, are sufficient to go to the jury as circumstantial evidence.”

In an early Ohio case the evidence showed that a farmer represented himself as a cancer doctor, having skill and experience in the treatment and cure of cancers, and claimed also to be in possession of a certain recipe or prescription, procured from a certain cancer specialist, that would remove cancers without affecting

sound tissue. This evidence was considered sufficient to render him subject to the same liability as a qualified physician in the treatment of a malady of the character he professed to treat.*

And in a more recent Illinois case one suffering from an injured finger went to a druggist for treatment, supposing him to be a physician. The druggist treated the finger wrongly, which resulted in an aggravation of the injury and final loss of the finger.

The court was of the opinion that the druggist, by treating the finger, the plaintiff believing him to be a doctor, held himself out as such, and was consequently chargeable in that character;†

**General Scope of Physician's Liability.—Questions of liability immutable in their nature and character may, and indeed do, arise, both from an inadvertent and from a willful violation by the physician of his duties and obligations to his patients. The cases heretofore considered are those in which the physician has failed to treat his patient with proper skill or care, or has been deficient in performing some duty nearly related thereto. An examination will soon be made of a few cases arising from acts either of omission or of commission, which contravene duties of a wider scope that he owes to his patients or employers. It will be observed, however, that in many of the illustrations following the familiar principles heretofore discussed will be involved.

**Necessity of Consent to Surgical Operations.—As a general proposition of law, a surgeon must have consent before operating upon a patient. As a matter of law, however, the courts are disposed to imply consent to perform the particular operation from the fact that the patient has placed himself under the surgeon's care. A recent English case, which has justly provoked considerable unfavorable comment, is that of Beatty vs. Cullingsworth.‡ In this case the plaintiff, an unmarried woman, who was about to submit to the operation of ovariotomy, told the defendant, who is said to be one of the most eminent London surgeons, that if both ovaries were found to be diseased he must remove neither. He replied, "You must leave that to me." The plaintiff denied hearing this remark. Both ovaries were found diseased and were removed.

The plaintiff was engaged to be married, but upon learning that both ovaries had been removed broke her engagement, and later brought suit against the surgeon for malpractice. Justice Hawkins, upon the trial of the case, charged the jury in effect that the plaintiff had tacitly consented to the operation, whereupon they returned a verdict for the defendant. A prominent legal journal, in commenting on the case, says: "The action of the court in this case has met with very general criticism upon the ground that the facts involving a direct prohibition would seem to exclude the possibility of implying consent. As a contemporary says, it is one thing for a surgeon to refuse to operate unless unlimited discretion is confided to him and quite another thing to deliberately disobey express instructions. Undoubtedly the defendant's wisest course would have been to refuse to operate unless the scope of his authority was agreed upon in advance." §

This case can not be safely considered the law in this country, for an American court would not, it is thought, instruct the jury, under like circumstances, that there was a tacit consent to the operation, but would leave it for the jury to determine whether the evidence before them showed a tacit consent. In short, in nearly all cases of this sort the question is one of fact, for the determination of the jury, rather than of law.

An important question of law arises, however, when an operation is performed upon a wife or upon a child, as to whether or not the surgeon must first secure the consent of the husband or parent. In a well-considered case the court of appeals of Maryland denies that a husband has the right to withhold his consent to the performance of a necessary surgical operation upon his wife. The court, speaking through Justice Yellott, said: "Surely the law does not authorize the husband to say to his wife, You shall die of the cancer; you can not be cured, and a surgical operation affording only temporary relief will result in useless expense. The husband has no right to withhold from his wife the medical assistance which her case might require." †

Following the reasoning of this decision, one can not see why a physician should be required to secure the consent of a parent before operating upon a child, provided the child was of proper age and discretion to understand the nature and effect of the operation proposed. As there seems to be no precedent upon this particular point, the question can not be authoritativey answered until a case involving the question shall arise which the parties thereto think sufficiently important to take to a court of last resort.

(To be continued)

**Pith of Current Literature.

Trophic Disturbances of the Bladder following Gynecological Operations.—Mirabeau (Centralblatt für Gynakologie, 1899, No. 11; American Journal of the Medical Sciences, August) calls attention to the fact that the vesical irritation so often observed after operation is usually referred to infection or mechanical injury, while in a few instances it has been due to ligatures which have made their way into the bladder. He reports two cases of colicotomy, with persistent vesical symptoms, in which cystoscopic examination showed general anemia and atrophy of the mucous membrane, evidently due to circulatory disturbances, the arteries being abnormally small, while the veins were prominent. He inferred that the collateral circulation had not been established as usual after ligation of the vesical arteries. In these cases treatment of the bladder itself may do more harm than good. Massage, the separation of adhesions, and softening of exudates in the neighborhood of the organ are indicated. As a prophylactic measure the surgeon should avoid mass ligatures and ligate the vessels separately so far as possible, sparing those which supply the bladder.

Hæmorrhage from the Septum Nasi.—Dr. Marcel Natier (Laryngoscope, August), in a paper on Three Cases of Spontaneous Hæmorrhage from the Septum,
says that when the source of the bleeding is located our action should always be to promptly check it. The means may be varied. Having no other means, we can bathe the parts in hot water, or use simple astriction, or tamponing. The flow being unilateral, it suffices to tampon the side from which it comes. It is rare that it is necessary to plug both the anterior and posterior nares. If the blood comes from the anterior part of the cavity, it is necessary to apply the plugs at that level, and to notice if the flow stops. But this is not radical treatment. A permanent cure is to be effected only when the cause has been removed. The point to be aimed at is to transform the ulcerated and friable mucous membrane at the level of which the blood flows into cicatrical tissue. This can be accomplished with either nitrate of silver, chronic acid, or the galvano-cautery. From conviction the author always employs the latter, and always successfully. The instruments are simple, and one can have them constantly available for either office or outdoor practice. If the battery is not available one could use the chronic acid or silver. But, in the author’s opinion, the actual cautery, as represented by a probe heated red hot over a spirit lamp, is preferable.

Serum Therapy in Tuberculosis.—Dr. C. P. Ambler (Journal of the American Medical Association, July 8th), in a paper read before the American Medical Association at Columbus, reports one hundred and six cases of tuberculosis treated during the year 1898 by serum therapy in conjunction with climatic and strict hygienic supervision of the patient. The author says that in presenting this report of cases he wishes to place himself on record in attributing the results obtained to these three factors in the order named.

The most rigid observations of all directions as to hygiene, following closely what has been found after several years’ experience in institutional work to be the best for this class of patients, have been insisted on. This has included particularly the avoidance of over-exertion; the regulation of diet; exercise and rest in bed; the observation of temperature and pulse; regulation of excretory functions; instruction as to the time for eating heaviest meals; time to elapse between meals; cold bathing; proper dress; fresh air; breathing exercise; taking of stimulants; sexual indulgence; and in fact all those little things which in themselves once occurring are nothing, but which often repeated, and carried to excess, have a marked influence on the well-being of the patient.

The climate of Asheville has been, in the author’s opinion, of valuable assistance. The author’s experience with serum has extended over two years in a private practice devoted to the treatment of tuberculous diseases. His classification of cases is not in the usual set of “stages,” but in Class A he records all those cases which in his opinion had, on commencing treatment, a fair prospect of recovery. In Class B he includes those cases in which great improvement might be expected, but a complete recovery was doubtful. In Class C are placed cases presenting such complications or extensive involvement as to preclude much encouragement being given.

Under this classification the author has considered the patient’s chances from all points of view: his physical condition, history, temperament, hygienic habits, surroundings, and his financial condition. This latter, says Dr. Ambler, may seem a cold-blooded cause for classification, but nevertheless in all cases it becomes of importance. For instance, one case in Class A could not have been so classified (cavity being present) if the patient had not been financially able to refrain from work and conduct herself as one with a rapid heart must necessarily do if recovery is to be expected. Again, one case in Class C could have been placed in Class B had the patient been able to stop work. As it was she was a charity patient, compelled to work to pay her board, and did not do well.

Class of Cases in which Serum is Indicated.—The use of antitubercle serum would seem to be indicated in the incipient cases, and more especially in those presenting a simple infection. Good results have also been accomplished in a majority of the cases classified under Class B, while in advanced cases the progress of the disease can often be temporarily arrested and distressing symptoms relieved, but the remedy, even under most favorable circumstances, fails as everything must fail, to bring about recovery in such cases.

Contraindications.—Generally speaking, the use of antitubercle serum seems to be contraindicated in cases of miliary tuberculosis, in cases of extensive softening, high pulse, marked emaciation, or decided hereditary history. This means that these cases will, in all probability, progress, no matter what form of medication is used. As a rule, the injections have not been given where the temperature reached a maximum of over 101° F. daily, the author’s experience having been that such a temperature in an early case was invariably the result of some indiscretion on the part of the patient.

Advantages over other Forms of Medication.—The hypodermic injection of the remedy precludes the possibility of direct interference with the processes of digestion and assimilation. The absence of medication by the stomach is, with proper instruction as to diet, certainly to the advantage of the patient. There is less indigestion, less flatulence, less bowel complaint, and invariably a better appetite with corresponding power to better digest and assimilate a full meal of ordinary bread-stuffs.

The author’s experience corresponds exactly with that of Dr. J. Edward Stubbert, of the Loomis Sanitarium for Consumptives, in that the bacilli disappear from the sputum long before the latter has entirely ceased. Relapses during treatment and after are much less frequent than under any other form of medication Dr. Ambler has ever tried. This in itself means much when it is remembered that in the usual course of tuberculosis the disease is one of relapses.

Patients cited as “cured” have returned to their homes, and in no instance, to the author’s knowledge, has a case in Class A relapsed up to this time, notwithstanding that many are in unfavorable locations and others are back at work. Whether, says the author, a certain degree of immunity has been established, or whether the elimination of the tuberculous products has been more certain, the fact remains that serum patients do not relapse like those treated with cresote and other allied drugs.

Furthermore, during the entire time that these one hundred and six cases were being treated, but two patients had hemorrhage serious enough to warrant calling a physician, while fifty-five gave a history of having bled prior to the time of beginning treatment.

Night sweats have been more easily controlled. During the weeks and months necessary for the contraction and cicatization of small cavities, the patients
have remained free from distressing symptoms, and have not shown the symptoms of relapse or involvement of new tissue.

As a rule, Dr. Ambler has observed that the expectoration materially increased during the first two weeks of treatment, and then rapidly diminished in the favorable cases, changing in character as well as in amount, becoming lighter, losing its purulent character, and finally appearing as a gelatinous mass. In the far-advanced cases, or in those with extensive cavity formation, this influence on the expectoration was usually negative.

Length of Time to be Administered.—The injections have been continued in those cases reported as "cured" for several weeks, and in a few cases for months, following the disappearance of tubercle bacilli, the microscopic examination being frequently made during this time. In this class of patients no unpleasant symptoms have followed the long-continued use of large doses.

Accidents following Administration.—In about fifty per cent. of all cases treated a local erythema occurred over, and in the point of injection, during the first week. In a small percentage this erythema became more general, and in three cases was well marked from the waist to the feet. After the first week no such local or general redness of the skin followed the injection. Local swellings at the point of injection and occasionally at adjacent joints, pain in the joints, and itching of the skin were frequently complained of for the first few days. When enlarged lymphatic glands have been present, especially the cervical and axillary glands, these have invariably been found to enlarge and become tender during the first two weeks, and if not casous, they have then gradually diminished in size and finally disappeared entirely.

The symptoms mentioned above are not serious, says the author, but only annoying to the patient. The only really serious symptom observed by the writer has been a sudden attack of syncope occurring in from one to five minutes following injections and lasting about two minutes. This has occurred in five per cent. of all cases, being accompanied by flushed face, followed by pallor, weak heart, pain in the back, nausea, and in one case violent vomiting, and is believed to be due to the injection of the serum into a small vein. This distressing symptom passes off in a moment on placing the patient in a recumbent position, and, so far as Dr. Ambler can determine, has never been detrimental to the patient.

On account of these local and systemic symptoms the author has made it a rule to begin with a small injection, 0.2 cubic centimetres, gradually increasing to 0.5 cubic centimetres, remaining at this dose for a few days, and then gradually increasing to one cubic centimetre, rarely exceeding two cubic centimetres at a dose, the injection being given daily in the loose skin above and behind the crest of the ilium, using a cubic centimetre graduated syringe with the smallest sized Green hypodermic needle. The use of such fine needles for serum therapy compels the greatest possible attention to the instrument in order to keep the needle patent; hence the fine needle is not only more agreeable to the patient, but more liable to be rendered aseptic in order to be of service.

Serums Used.—Serums from three different manufacturers were used, the whole amount being approximately eight thousand cubic centimetres. Having in the course of a very few months observed decidedly the best results from the use of Fisch's antiphthisic serum. T. R., the others were discarded; altogether about six thousand cubic centimetres of Fisch's serum were used. This product, Dr. Ambler says, has invariably proved stable when properly handled, in but two bottles cause for complaint being found, due in both instances to infection from loosening of the stopper during transit.

Remarks.—The use of antistreptococcic serum in conjunction with antitubercolar serum in the author's hands has not proved of much benefit. Streptococcic have disappeared in favorable cases without it, and in advanced cases have remained, no matter whether it was given or not.

The following is a summary of the author's cases:

In Class A (numbering 46 cases) in 35, or seventy-six per cent., cough and expectoration disappeared, while in all cases they were diminished; bacilli disappeared in 41, or eighty-nine per cent.; weight was gained in 44, or ninety-six per cent., and vital capacity increased in all cases; temperature and pulse became normal in 44, or ninety-six per cent.; 25 cases, or seventy-six per cent., were apparently cured; 9, or twenty per cent., greatly improved; 11 improved; 1 remained stationary; none grew worse or died.

In Class B (numbering 28 cases) cough and expectoration disappeared in 3, or eleven per cent., and diminished in 19, or sixty-eight per cent.; bacilli disappeared in 8, or twenty-eight per cent.; weight was gained in 26, or ninety-three per cent.; and vital capacity in 27, or ninety-six per cent.; temperature and pulse became normal in 17, or sixty-one per cent.; 6, or twenty-one per cent., were apparently cured; 13, or forty-four per cent., greatly improved; 8, or twenty-eight per cent., improved; none remained stationary; 1 died.

In Class C (numbering 32 cases) cough and expectoration disappeared in none, were diminished in 18, or fifty-six per cent.; weight was gained in 22, or sixty-nine per cent., and vital capacity in 25, or seventy-eight per cent.; temperature and pulse became normal in 10, or thirty-one per cent.; none were apparently cured; 9, or twenty-eight per cent., were greatly improved; 3, or sixteen per cent., improved; 6, or nineteen per cent., remained stationary; 11, or thirty-four per cent., grew worse; and 1, or three per cent., died.

The Uses of Hyoscyamine.—Dr. J. T. Fotheringham (Canadian Practitioner and Review, July) thinks that hyoscyamine is not used so frequently as its merits, in properly selected cases, would justify. The salt commonly employed is the hydrobromide in doses usually of one-hundredth of a grain. The profession at large is aware that it is used in the asylums for the insane, in manical cases, but is not aware of the valuable service it can render in general practice. The author has, within the past five months, used it with marked benefit in several cases widely differing in character, and has been impressed with its good results.

Dr. Fotheringham then gives abstracts of his five cases. The first was that of an old lady of eighty who feel rapidly into a state in which death seemed imminent, very slow and irregular pulse, dry, brown tongue, obstinate wakefulness and night terror, long fits of screaming, with almost total suspension of assimilation and excretion. Hyoscyamine hydrobromide, one one-hundredth of a grain by mouth in the evening, repeated it two hours when necessary, with another hundredth of it.
grain in the morning, controlled this cortical activity excellently and promptly whenever given, and in two weeks or so, with nux vomica and proper attention to feeding and excretion, with the occasional use of a mixture containing digitalis, nitroglycerin, and ammonium bromide, she made an excellent recovery. The second case was that of a woman of sixty-seven who developed meningitis on convalescence from pneumonia. The third case was one of mild hysteria in a young married woman. The fourth a case of severe hysteria in a girl about eighteen. The fifth was a case of acute rheumatic exacerbation of an endocarditis, long previously existing, in a young man of about twenty. There were sleeplessness and delirium accompanying circulatory disturbance in the brain.

The author says that cases even so divergent as these do not indicate the whole range of usefulness of the drug. He says that it is "certainly of great value in spermatorrhoea and nocturnal emissions." Also that it acts mainly on the cerebrum (he might have said the cortical areas), and that "it is of value as a hypnotic only in a very limited class of cases, but in this class generally acts most favorably." These are cases of insomnia due to acute mania, delirium tremens, hysteria, or similar cause—one might say, perhaps, cases in which there is functional overactivity of the higher centres without undue depression of the vegetative centres; for experience in insane asylums has shown it to be injurious to melancholies, and in general paresis, chronic mania, epilepsy, and dementia it is no better than chloral, but is apt by constant use, at least in some cases, to increase excitement. Peterson (New York Medical Journal, October 11, 1890) found it very efficacious in controlling the tremor of paralysis agitans.

Objections to the drug are, first, the uncertainty of its action, a peculiarity common to all drugs the brunt of whose influence falls upon the nervous system. Idiosyncrasy may cause alarming cardiac, respiratory, or spinal depression. Like all drugs from the atropineaceae, it dilates the pupil, dries up the throat, and if pushed may cause dizziness, delirium, and an erythema of the skin. Some authorities have insisted that it must be given by hypodermic injection, but the writer has seldom so used it, and has been amply satisfied with its action given by the mouth. It may cause croupy breathing, probably from laryngeal dryness, and, in spite of the benefit evident in a case of insomnia from cardiac disease which is detailed, it is usually considered less safe than morphine in such cases.

The Treatment of Vaccination Sores.—Dr. A. K. Bond (Maryland Medical Journal, July 1st) says that the belief prevails in the community that a sore half an inch or more in diameter suppurating for weeks, or even for months, is an occasional sequel of successful vaccination which must be borne with patience, and is to be treated as well as may be with dressings of mild powders and salves of various sorts. The exposure of this error is the author's motive for writing. He knows by experience in their treatment that the most reputable dressings of such sores may be caused to cease suppurating and to become a dry-scabbed sore in even a single painless dressing and may be healed within perhaps a week. At first he supposed that this fact was known to the mass of practitioners, but apparently it is not. The dressing referred to is a solution of nitrate of silver, about eighty grains to the ounce of distilled water. When such a sore is brought to him he removes the scab, if it has one, washes the surrounding skin clean, perhaps using alcohol, and mops the sore carefully with the silver solution until its surface is covered with a thick layer of white. When this has dried, a dressing of absorbent cotton with bismuth, or what not, dusted on it is applied. The pain of the silver in this strength is insignificant, the itching and irritation greatly diminish or disappear, the suppuration is permanently, or for many days, stopped, and the patient almost forgets the sore. In some cases the dressings begin after a week or more to become soaked with pus. A second nitrate-of-silver application may then complete the healing.

Proceedings of Societies.

SOCIETY OF THE ALUMNI OF THE CITY (CHARITY) HOSPITAL.

Meeting of April 12, 1890.

The President, Dr. William L. Stowell, in the Chair.

The Effects of Influenza on the Eye.—Dr. H. S. Oppenheimer read a paper on this subject. (See page 225.)

Dr. A. T. Muzzy said he should not attempt to give any extensive statement after such an exhaustive paper. He had listened with a great deal of pleasure to the review of the conditions resulting from this very widespread affection, and the many forms of eye trouble that may follow. In his own experience he had not met any of the severer forms of eye trouble coming on from influenza. Those that had fallen to his lot had been the lighter forms of keratitis and paresis of muscles. In the epidemic of 1889 his experience seemed to run almost wholly to conditions of the cornea and conjunctiva, and, while they did not seem to differ from keratitis coming from other conditions, they had one characteristic which did not coincide with the mass of material that Dr. Oppenheimer had given—namely, they yielded promptly to treatment. The epidemic this past winter had shown, on the other hand, in his experience, an entirely different form of affection, being characterized almost wholly by affections of the muscles of the eye, heterophoria. These cases under proper treatment and proper glasses were completely relieved, the muscular balance returning to a normal condition. He thought the inflammation of the globe arose from a very widely disseminated constitutional condition, and when it affected the eye it showed itself more from the irritation of the circulation; but this winter the cases coming on from milder cases of grippe were followed by light forms of paresis, which disappeared under proper tonic treatment of the eye as well as of the general health.

Dr. Adolph Rupp said that as a general practitioner he had not been obliged to send any of his grippe cases to the ophthalmologist; they generally got well under ordinary treatment. The cases reported by Dr. Oppenheimer were interesting, and had made him think of possibilities that might occur—for instance, he recalled some cases that later on he had sent to the ophthalmologist that might possibly have been caused by the grippe influence. From the bacteriological discussion of the
matter, it would seem that the gripe bacillus, whatever it is, probably the smallest of all the bacilli or cocci, has not been the only influence, but that the pneumococci and all the cocci had something to do with it. It was hard to distinguish whether all these bacterial influences were not merely coincidental and not causative.

Dr. Oppenheimier said that when he used pilocarpine he usually had the patient lie down in bed, and gave it hypodermically in small doses, increasing the amount cautiously, because it had a decided depressing influence on the heart's action. It was wise to have a quick stimulant on hand to inject in case there were unpleasant consequences. He found that the more perspiration he could induce the better the results. He had seen some rather alarming symptoms in two different cases, which made him very careful in the injection of pilocarpine, always having the patient in a recumbent position, and giving whisky or ammonia, or some other stimulant, ready.

A Codfish Bone removed from the Anterior Abdominal Wall.—Dr. Fielding Lewis Taylor presented a specimen which appeared to be a rib of a codfish, about an inch and a half long, slightly curved, sharply pointed at one end and broken off obliquely at the other. A woman, aged fifty years, came into the clinics at the Hudson Street Hospital and stated that she had a tumor in the side. Examination showed a tumor of about the size of an egg situated in the left nipple line, about three inches below the free border of the ribs, and adherent to the skin. No tenderness was present. She said that she had had syphilis and that her family physician thought this was perhaps a return of her old trouble. She was given mixed treatment. About ten days later she returned and said that she had recently suffered much pain in the tumor, and that morning she had found the specimen presented projecting and had pulled it out. Upon further questioning, she said that she had eaten some codfish about five weeks before and had experienced considerable pain in the stomach for many days afterward. Examination showed the tumor was broken down at its centre, and a probe showed the existence of a narrow sinus.

(To be concluded.)

Book Notices.

The second volume of this periodical contains very thorough consideration of all recent matters in the fields of abdominal surgery, gynecology, blood diseases, diatheses, and ophthalmology. The contributions are all characterized by editorial ability and are fully in keeping with the standard established by the first volume. Among a number of similar publications it is difficult to choose, but certainly there is none the superior of Progressive Medicine.

It is a pleasure to call attention to the fourth edition of this estimable work. As compared with the third edition, it shows the moderate amount of revision that a brief period of time might be expected to require; the additions, however, are not numerous. As everybody knows, the work is one of the best of its class.

An interval of four months between the appearance of an edition of a medical work and its exhaustion would indicate the value of the work and would presuppose that the second edition would be little more than a reprint. The first of these indications is amply justified, and we have already expressed our high opinion of the worth of the book. The second assumption, however, is far from being warranted in the present instance, for the edition before us is little short of a new work. We do not mean that the features we found commendable in the first edition are lacking in the second, but much has been added to them, with the result that the later work becomes both more pretentious and more complete. Not to enter unnecessarily into details, the additions are to the credit of the author, particularly those referring to cerebro-spinal diagnosis by the hand and to the clinical significance of the several forms of tremor.

The last edition of this work was published in 1896, and since that time the additions to the class of synthetic remedies have been exceedingly numerous. For this reason and the appearance of a third edition of the book is a matter of importance to all therapeutists who make any pretension to “keeping up” in their reading. The list of drugs afforded by the book is most complete, and
the information as to chemistry and composition, action, and dose is given with brevity and clearness. Not only are true chemical compounds described, but many of the various proprietary mixtures with which the market abounds. In the present edition there have been added a brief descriptive chapter of the remedies prepared from animal tissues and another on the indifferent compounds of iron. The importance of these additions is self-evident. The book, in our opinion, is one of the greatest value and usefulness. Indeed, it is difficult to see how one can keep in touch with modern therapeutics unless some work like this is constantly at hand for reference.

The fourth edition of this well-known handbook preserves the valuable features of its immediate predecessor while containing a considerable proportion of added matter that the progress of the forms of treatment with which it deals has required. As has been apparent by the favorable reception accorded to the earlier editions, the work is to be rated as most excellent.

_International Directory of Laryngologists and Otolognists._ Containing Names and Addresses of Practitioners engaged in the Study and Practice of Laryngology and Otology. Compiled by RICHARD LAKE, F. R. C. S. Published under the auspices of the Journal of Laryngology, Rhinology, and Otology. The Rebman Publishing Company, 1899. Pp. 111. This little book will doubtless prove of service to practitioners whose patients are given to travel. It contains a fairly complete and accurate list of the various specialists in laryngology, rhinology, and otology, arranged in alphabetical order, with the cities in which they practice appended to their names; and in a second division the principal cities of Europe and America, and a few in Asia, follow in alphabetical order with the practitioners' names and addresses in like order.

_Distilled Water as a Beverage._—The following practical editorial remarks appear in the American Kitchen Magazine for July:

"There is a difference between a beverage and a medicine, and while no one will dispute the fact that there are many cases in which the use of distilled water by a physician's direction has proved of value, there are many reasons why the habitual use of distilled water as a beverage may not be beneficial.

"Many firms with a shrewd eye to business have taken advantage of the 'microbe scare' to place upon the market various forms of distilled water, and have not hesitated to make certain statements, which would be remarkable if true, calculated to attract attention.
Certain persons with a sincere idea of benefiting mankind have seen that it was easier to influence ordinary people in regard to articles of drink than in regard to their daily food habits. Thus hundreds of persons will faithfully drink lithia water when they would not submit to a diet which might accomplish the same purpose.

"Similarly the use of distilled water on the table is much simpler than the banishment of certain articles of food or the restriction of an overactive appetite to the needs of an underactive life.

"Water is the universal solvent, and in the human body it carries both food to and waste from the cells and tissues. Water has a selective action in that it dissolves more of some substances than of others, and it drops out one set of salts in the presence of other salts. But, on the other hand, water containing a portion of one salt often dissolves more of another than if it were pure. Water containing common salt dissolves globulin, vitellin, and certain other animal nitrogen substances which are not soluble in pure water, and it is probable that this property has some bearing in the animal economy.

"Distilled water taken on an empty stomach would tend to leach out the cells with which it came in contact, and we know that the life of the cell depends upon the maintenance of its contents at a certain standard. This is a well-established fact and not, as one advertisement implies, a vision of a mad microscopist. The testimony of physicians that the prolonged use of distilled water has a tendency to decrease the body weight shows a lessening of nutritive power in the tissues.

"Most persons eat enough salt on their food to bring up the average, and many persons in middle life and after, eat too much of all kinds of food and drink too little fluid, so that for them a course of distilled water may be most beneficial, carrying away an excess which would be harmful.

"Since it is true that the same person may assimilate himself to the softest waters of the Atlantic coast after having lived for years in the limestone region of the West, where the water contains one hundred times as much mineral matter, and vice versa, it will be seen that habit has much to do with the case. The system soon adjusts itself to the demands made upon it unless it is enfeebled by abuse.

"If an individual over forty is living on potatoes pared before cooking, white bread, unsalted butter, cream, fruit, and sugar, then distilled water would be superfluous if not harmful; but if the diet is rich in meat, in cereals, in milk, and abundant at that, it is very probable that distilled water would remove more of the excess than would a hard water taken as a beverage."

The Liverpool School of Tropical Diseases Research Expedition to West Africa.—We learn from Science for August 4th, quoting the London Times, that the Colonial Office writes that "Mr. Chamberlain had learned with great satisfaction that the expedition of the Liverpool school is being sent, and appreciates the energy and public spirit shown by the committee of the school in the matter. The authorities at Sierra Leone will be instructed to give every facility to the work of the expedition." The colonial office have also sent for the use of the school valuable medical and sanitary reports of various tropical colonies, and the India Office have sent their medical publications. The British Museum directors have been invited to send with the expedition their diptero-ologist, Mr. E. E. Austen, offering to pay his expenses. The expedition is expected to throw an important light on the theory held by Major Ross and others as to the propagation of malaria by mosquitoes. The expedition was to start on July 29th and proceed direct to Sierra Leone, and will set to work at once in a district which then happens to be peculiarly unhealthy. It is intended afterward to make investigations at Accra. The Belgian government have sent an officially appointed delegate, Dr. S. Van Neck, to visit the Liverpool School of Tropical Diseases and accompany the expedition.

Concerted Sanitary Action in Australasia.—According to Science for August 4th, the Australasian Association for the Advancement of Science has received general support from the various provincial governments for its recommendations: 

a. That a system of compulsory notice of infectious diseases be introduced.

b. That a system of federal quarantine be introduced.

c. That stock, the milk or flesh of which is intended for consumption, be examined by duly qualified men, and slaughtered, if found tuberculous or cancerous.

Death of a Veteran Physician.—From the Medical Times for August we learn that Dr. William Russell, of the class of 1836, the oldest Harvard graduate, died recently at the age of ninety-nine, being, we understand, a practising physician.

The Occidental Medical Times.—The Occidental Medical Times, formerly published in Sacramento, has now amalgamated with the Pacific Record of Medicine and Surgery. The title of Occidental Medical Times is retained, but the publication office is removed to San Francisco. Dr. James H. Parkinson remains the editor, and associated with him is Dr. Louis A. Kenga, editor of the Record.

Naval Medical Men of the University of Virginia.—A medical officer of the navy sends us the following:

"In comparing the representation of the several colleges in each State, as seen in the medical corps of the navy, the University of Virginia may be said to stand first. I shall not attempt to give a history of the life of each individual, but of those I know I shall give a few sketches of their careers as naval surgeons. Taking them in the order of seniority, let us begin with the fleet surgeon under Admiral Dewey's command at the battle of Manila Bay.

"Dr. John C. Wise received the greater part of his scientific education at the University of Virginia, and he openly asserts that he owes his success to its thorough teaching. Born October 7, 1848, in Accomac County, Virginia, he attended the schools of the Reverend James D. Gatewood and the Reverend James Herbert, in Norfolk, from 1857 to 1861, entered the University of Virginia at the session of 1867-'68, and became a member of the Delta Pi fraternity. Graduating in medicine, he was elected by the faculty adjunct professor of hygiene and medical jurisprudence at Bellevue College and resident physician of the College Hospital. He was appointed assistant surgeon in the navy in March, 1870, and was the first Southerner appointed after the civil war. His first duty was on the Guerriana, on the European station. He served at the navy yard at Norfolk in 1874, and was promoted to passed assistant surgeon the same year. He was on the Dispatch (stationed at Constantinople) during the Turco-Rus-
sian war of 1875–76. Returning home, he was ordered to the Minnesota. He was promoted to be surgeon in 1882, and ordered to torpedo station and from there to the Asiatic station, where he remained until 1883, when he was made a member of the board of inspection and survey. He retired on this duty until his promotion to be medical inspector in 1896, when he was appointed naval delegate to the Association of Military Surgeons, and in 1897 he was elected vice-president of that association. He was then detailed as fleet surgeon of the Asiatic station and participated in the fleet action in Manila Bay on May 1–3, 1898.

"Dr. Presley Marion Rixey was born in Culpeper County, Virginia, in 1852, received his diploma as doctor of medicine from the University of Virginia in 1873, attended hospitals and other clinics in Philadelphia, and entered the navy in 1875. His first duty was on the Sabine, and his next was at the Norfolk navy yard, 1877–79, from which station he was ordered to the Tallapoosa, after which he was given special duty in Washington, where he has continued to serve, except when ordered on sea duty, until the present time. He was decorated with the Order of Naval Merit by Alphonso XIII for services rendered to the officers and crew of the caravel Santa Maria on the occurrence of an explosion on that vessel in New York harbor in 1893.

"Dr. L. G. Henneberger was appointed from Virginia assistant surgeon in 1874, promoted to be passed assistant surgeon in 1877, and was on duty in the James River in 1878, and on the European station and at the Washington navy yard in 1884. He was attending physician to the families of naval officers in New York until 1888. He was promoted to be surgeon in 1890. He was ordered to the battleship Maine in November, 1897, and was attached to and on board that vessel the night of her destruction in Havana harbor. After this he was on duty with the survivors of the ill-fated Maine at Havana until March, 1898, when he was ordered to Washington. During the Spanish war he was made surgeon of the St. Paul.

"Dr. Charles T. Hibbett, a graduate of the University of Virginia, is a Tennessean by birth. He received a commission as assistant surgeon in the navy in January, 1875, and was promoted to be passed assistant surgeon in April, 1880, and to be surgeon in December, 1892. Although born in Tennessee, he is a Virginian by adoption and has many interests in and about Norfolk and Portsmouth.

"Dr. James D. Gatewood, now on the Lancaster, is a graduate (in medicine) of the University of Virginia, and is a native-born Virginian. Dr. Gatewood received his degree as M. D. in 1879, and was appointed assistant surgeon the following year. He has been of material assistance in prosecuting the departmental revision and perfection of the medical corps. During the late Spanish-American war he was attached to the monitor Puritan, and after hostilities ceased he was sent as special agent of the bureau to inaugurate the naval hospital in Havana.

"Dr. Henry B. Fitts, born in Petersburg, Virginia, in 1855, was graduated in medicine from the University of Virginia in 1889; he also enjoyed the opportunity offered him to take a post-graduate course at the University of Pennsylvania for the period of two years; he then entered the navy, in July, 1882. His first assignment was to Norfolk, whence he was sent to sea on the Jamestown, and his next duty was with the coast survey. He then served in the New York and Philadelphia hospitals, and from 1887 to 1890 he was stationed at Sitka. From this station he went to the Army and Navy Hospital at Hot Springs, Arkansas, where he served until 1894. Then he was ordered to the Essex, and in 1897 to the naval hospital at Portsmouth, New Hampshire. His father was a lieutenant in the Confederate army, and was killed while in camp near Norfolk.

"Dr. Joseph Alfred Guthrie, passed assistant surgeon, is a son of the late John Julius Guthrie, formerly a lieutenant in the United States navy and during the civil war a commander in the Confederate navy. After the civil war Commander Guthrie was appointed by General Grant a superintendent of life-saving stations (Atlantic coast). In this capacity it was that he lost his life in attempting to save the lives of those on board the ill-fated United States steamer Huron. Dr. Guthrie was appointed, in May, 1883, to the naval academy by a friend of his father (President Arthur). He resigned a year afterward and studied civil engineering in Philadelphia. He entered the University of Virginia, Scientific School, in 1887, graduated in chemistry, and then in all the branches of medicine, and received his degree of M. D. in June, 1890. He attended the Postgraduate clinical courses and Bellevue Hospital, in New York, up to December, 1891, when he received a commission as assistant surgeon, and served first at Port Royal, South Carolina. He is a member of the Association of Military Surgeons of the United States, of the New York Yacht Club, and of other organizations.

"Dr. Moulton K. Johnson, born December 4, 1869, in Cincinnati, was educated in the high schools and technical schools of that city. He entered the naval academy in June, 1889, resigned in 1893, and studied medicine at the University of Virginia. He received the degree of M. D. from that institution in June, 1895. He was commissioned as assistant surgeon in the navy in the following November, and ordered for duty at the naval laboratory, New York. From there he went to the Franklin, and next to the coast survey steamer Beech. He has been attached to the New York and the Vicksburg recently. In 1898 he was promoted to be passed assistant surgeon, and his present duty is at the New York naval hospital.

"The present assistant surgeon-general, Dr. J. C. Boyd, is a University of Virginia alumnus, though not a graduate of the medical school. He has rendered an excellent account of himself during our late war with Spain, carrying on the rush of departmental business to a satisfactory termination. He holds his position because of his peculiar adaptability and gift of extraordinary executive ability.

"In 1890 there graduated in medicine at the University of Virginia four naval academy graduates—viz.: Richard Jackson, M. R. Pigott, L. L. Young, and W. B. Moseley. Two of these afterward entered the navy as assistant surgeons, and have since done credit to the Virginia school. Dr. Jackson, who is a son-in-law of Admiral Sampson's, was taken back into the line for conspicuous and heroic conduct during the gale that destroyed our fleet at Samoa. He is now a lieutenant of the line, although holding a diploma as an M. D.

"Dr. Moseley's health failing, he was compelled to give up his first intention of entering the navy, and is now a very successful specialist in his native State of Texas.

"Dr. Young is a son of Judge Young, of Jackson, Mississippi, and his career in the medical corps of the
navy has been very creditable, both to himself and to the University of Virginia.

"Dr. Pigott, who is now stationed at Annapolis, is an expert in physical training and is considered a very brilliant physician. Much more could be said of these last-named gentlemen, but from their modesty in furnishing data it has been impossible to obtain enough to do them justice in a sketch of this kind."

To Test the Value of a Stethoscope.—Dr. N. A. Powell (Dominion Medical Monthly, July) says that in regard to physical diagnosis, if you wish to estimate the value of a stethoscope, take a watch and place it on the table, then with the back of the hand on the watch place the bell of the stethoscope in the palm of the hand and listen to the tick of the watch in this way. In examining a patient for early tuberculosis the stethoscope should always be used whose accuracy is above suspicion.

Another "Christian Science" Victim's Death to be Investigated.—According to the Medical News for August 5th, Mrs. Edward Flanders died of “blood poisoning” at St. Luke’s Hospital, Chicago, on July 29th, after having been attended by Mrs. Bratz, a "divine healer." The State board of health of Illinois has notified its attorney to investigate the case.

The Central College of Physicians and Surgeons, of Indianapolis.—In our issue for July 29th we remarked upon certain newspaper reports of disagreements that had led to the resignation of some members of the teaching corps. We learn from the president of the faculty, Dr. Joseph Eastman, that those who resigned were for the most part incumbents of unimportant or duplicate chairs, and that the institution has not suffered from their action.

English versus American Athletes.—It is of interest to note that in the recent athletic contest between the representatives of English and American universities, the Englishmen won those events which called for physical endurance, whereas the Americans were successful in the contests requiring special strength and skill, without prolonged muscular effort. In no case did the Americans win, or come very near winning, any of the long runs, whereas in short distances, the one-hundred-yard dash for example, a supreme effort in the last few yards brought the American representative in ahead of his English competitor. The hurdle race also, requiring much skill, combined with temporary effort, was easily won by an American. The result of the longer runs might have been different had the man upon whom the Americans depended not been somewhat out of condition, but the fact remains that the English athletes had an endurance which was entirely lacking in our men. Whether this resulted from different training or climatic conditions or some more subtle cause, it is quite impossible to say, and certainly the data are as yet too few upon which to base conclusions. It is, however, to be hoped that this meeting, with a result so creditable to both sides, may be repeated each year alternately on this and on the other side of the Atlantic, and that an opportunity may thus be given, extending over a considerable period, of comparing methods of training and determining whether or not racial peculiarities or climatic differences underlie the rather striking outcome which we have had occasion to note this year. Some years ago a team of amateur English athletes visited this country and were thoroughly beaten. On that occasion they encountered, in addition to their opponents, excessively hot weather, which no doubt was a factor in the result. It is generally recognized, moreover, that a visiting team is always at a disadvantage.—Boston Medical and Surgical Journal, July 27th.

Christian (?) Science (?)—The New York Times quotes the following verses from the Chicago Living Church:

Oh, “God is so good,”
If we sit down and brood
On the goodness and “Allness,” within and without us,
We need have no fear,
Our crackers and beer
Will flow from the “Allness” and goodness about us.

Of course, “there’s no evil” —
God’s not so uncivil
To make us imperfect and send us to thunder.
“Ther’s nothing but love” —
In the heavens above,
The pockets of men, and the hearts that beat under.

“There can be no trouble” —
The body’s a bubble —
It’s all a “mistaken belief” and a dreaming.
God made us to fool us,
’Till some one should school us
To see what we see to be only a seeming.

“We’re nothing but spirit” —
We really don’t hear it,
Or see it, or taste it, or smell it, or feel it.

“There is no sensation” —
Except the temptation
To think what we think, when we think we can’t heal it.

’Tis quite a mistaken
Idea we have taken,
That there’s but one method of race propagation.
A child now to bother
About who’s his father
Shows stubborn contempt for the new revelation.

“Ther’s nothing but mind” —
Though created so blind,
We’re all of us nursing some little “delusion” ;
But friends by the score
(For a dollar or more),
Will kindly remove the distressing “illusion.”

With best of intention,
The Lord failed to mention—
While healing the halt and the deaf and the blind—
The trick of his healing
Was simply revealing
A “mortal deception” of “immortal mind.”

And that these signs and wonders
Arose from the blunders
The Father had made in creating mankind;
And, until he was ready
To send Mrs. Eddy,
The world must remain to his purpose blind.

Professor Sanarelli to come to America.—The Boston Medical and Surgical Journal for August 3d says it is reported that Professor Sanarelli will visit America to test the value of his yellow-fever serum in this country.
LOCALIZED TUBERCULOSIS OF THE
INTESTINE,

WITH A REPORT OF SEVEN OPERATED CASES.*

By W. J. Mayo, M. D.,
Surgeon to St. Mary's Hospital, Rochester, Minn.

Tuberculosis within the abdomen is of frequent occurrence, and clinical experience in abdominal surgery demonstrates that the disease as a primary infection is not uncommon, or, if not primary in all cases, the abdomen is, at least, the only locality involved in which it can be recognized.

The prevalence of tuberculosis of the bowel in children is shown by the statistics of Simms Woodhead. In a hundred and twenty-seven autopsies on children dying of tuberculosis the mesenteric glands were found to be involved in one hundred, and it is to be presumed that the intestinal was the primary lesion.

In the New York Pathological Society for November, 1898, Dr. R. G. Freeman reported a case of primary tuberculosis of the colon in a child and discussed the mooted point as to its frequency.

In adults the bowel infection is usually secondary. Five hundred and sixty-six out of one thousand autopsies held on the victims of tuberculosis in the Pathological Institute of Munich showed secondary involvement of the intestines, and in only one case was the disease primary. Hilton Fagge says that in twenty-five years at Guy's Hospital only one case of primary tuberculous ulcer of the intestine was found. He, however, notes some intestinal strictures which may have had such origin.

The frequency of primary tuberculosis of the intestine in children is believed by Osler to be due to milk infection; it has been shown by Ernst that the milk may be actively infected without disease of the udder. Adult foods, such as cooked meats, etc., are less dangerous as a primary source of disease.

The prevalence of pulmonary tuberculosis in the adult and the frequency with which sputum is swallowed accounts for the secondary nature of the intestinal deposits.

H. A. Tomlinson, superintendent of the St. Peter, Minnesota, State Hospital for the Insane, has had an exceptionally large experience in the pathological study of tuberculosis among the inmates, and, as the mentally deficient usually swallow the sputum, he has found secondary intestinal infection to be the rule.

Osler mentions the possibility of secondary bowel infection through extension from the peritoneum.

Dr. N. Senn, in a most exhaustive paper on Intestinal Tuberculosis published in the Journal of the American Medical Association in May and June, 1898, says: "That the disease may occur as a primary infection can no longer be doubted. The results of an enormous clinical experience and thousands of necropsies furnish a substantial verification of this fact."

It is hard to reconcile the divergent opinions of men of large experience as to the relative frequency of primary intestinal tuberculosis. With a view of ascertaining the relative proportion from the standpoint of the operating room, rather than the deadhouse, I have examined the records and printed reports of St. Mary's Hospital of our city for the past six years. I find the total number of operations classed as abdominal within this period to be one thousand and three, and of this number sixty-four have been for tuberculosis, divided as follows: Tuberculous peritonitis, thirty; encapsulated tuberculous collections of fluid forming an abdominal tumor, three; ovaries and tubes, eleven; appendix, seven; kidneys, seven; intestinal wall, six. The patients treated in this hospital are drawn almost entirely from an agricultural community.

The reports previous to 1893 contain but few cases in which the diagnosis was made, although I have reason to believe it was often met with but went unrecognized. This would give tuberculosis a place in abdominal surgery of about six and a half per cent. The six cases in which the intestinal wall was involved and in which the infection appeared to be primary would amount to six tenths of one per cent. of the total number. These few cases, with the addition of one case operated in at St. Mary's Hospital in 1891, form the basis of this paper.

Experiments have shown that the tubercle bacillus is not killed in the gastro-intestinal juices, and that it is able to penetrate the intact mucous membrane. Peyer's glands and the lymph follicles are the common seat of infection, but the process soon involves the submucous tissue and then ulcerates through the agency of a mixed infection. In primary tuberculosis the greater part of the involved tissue may slough, and by cicatrization a corresponding narrowing of the intestinal lumen take place.

The consequent interference with the progress of the intestinal contents may be the first symptoms of the disease. This form of obstruction in an acute stage led to operation in three of the reported cases.

In the causation of the symptoms the effects of secondary pyogenic infection is of the utmost importance. The peritoneum becomes thickened and boardlike over the ulcerated area, and to this point the neighboring coils of bowels may become attached, leading to kinking and partial obstruction, or form multiple intestinal fistulae.

A complete ulceration through all the coats of the intestinal wall protected by adhesions may allow of a
localized tuberculous pocket, giving the appearance of an abscess, as in Case V.

Rokitansky long ago pointed out the tendency of intestinal tuberculosis to follow along the blood-vessels and produce a circular deposit, as carcinoma is wont to do.

The healing process when established in such ulcers leaves a circular stricture. In secondary tuberculosis there is but little tendency to cicatization, and the extent of disease is usually larger.

Primary tuberculosis in children is less apt to ulcerate deeply, the rule being early involvement of the mesenteric glands, which in turn act as a distributing depot to the general system, either through the lymphatic channels or blood-vessels.

The experience of nearly all observers has been that in adults there is a distinct tendency for the primary disease to remain local, the prognosis, therefore, being far more favorable than in children. Senn points out the fact that in very many cases supposed to be primary there are other infected localities which may not be recognized.

The most common seat of primary tuberculous disease is in the ileo-cecal coil. The sigmoid and the lower ileum are also often affected, although any part of the intestinal tract may be involved.

Senn describes two forms of disease: one fibrous, with markedly great hypertrophy, resembling carcinoma, and an ulcerative variety, more apt to cause stricture. The two phases of disease are often present in the same case.

According to Hofmeister, multiple strictures are found only in the ileum. The appendix is often the starting point of the infection in the cæcum.

The diagnosis of secondary tuberculous infection of the intestines is usually easy, but this can not be said of the primary variety. In only two out of the seven cases herein reported was the diagnosis made. In Case IV the appearance was that of cancer, although tuberculosis was thought of.

In a general way it may be said that the ages of the patients range between fifteen and forty. In my own cases the youngest was eighteen and the oldest thirty-seven.

A tuberculous family history was present in only two, and was not marked in either case. The general appearance in the cases with obstruction was good up to the time of the sudden bowel stoppage, and in none of the cases reported has there been the cachexia of a cancerous affection of the same duration.

In the three cases having the largest extent of ulceration there has been some evening rise in temperature.

In the majority of cases alternating constipation and diarrhoea have been observed, and in the strictured individuals serious symptoms of obstruction have appeared several times before the attack of obstruction rendered relief imperative. In only one case was diarrhoea marked, and in this patient the cæcum and ascending colon were extensively involved. Diarrhoea would argue in favor of larger extent of ulcerated surface, and is common in the secondary forms of the disease.

The constant symptoms in all cases have been colic and colicky pains, and in five out of the seven cases urinary irritation was an annoying feature.

Fixation of the uterus with seeming enlargement of the ovaries and tubes led to operation in two cases. In each instance a peculiar change in the apparent size and consistency of the lateral masses was manifest on different days, probably due to the amount of retention of bowel contents above the stricture, and perhaps, also, as Dr. H. A. Kelly has pointed out, to the changing amount of fluids in the coincident pelvic disease.

Rigidity of the abdominal muscles, preventing accurate palpation, was also present in these two cases, and in the experience of the writer this peculiarity with an undue sensitiveness has been common in tuberculosis of the ovaries and tubes.

A well-marked tumor in the cæcal region was present in three cases, and this enlargement was nodular and apparently contained gas.

Examination of the stools for tubercle bacilli should be practised, although the limited extent of disease does not lead to frequent success. Sawyer says that the mucous membrane just inside the sphincters is most likely to contain the germs.

Rectal discharges of pus and blood should lead to a careful examination of the rectum and sigmoid by Kelly's method. I have under observation at this time a patient with marked tuberculous ulceration of the sigmoid detected in this manner.

Strictures resulting from the healing of tuberculous ulcers must be distinguished from the congenital and traumatic varieties and from those following the reduction of inflamed hernias.

Only one case in which a stricture followed typhoid ulceration could be found by Treves. Syphilitic stricture, according to Senn, is always fibrous and never ulcerative. Of the various forms, the carcinomatous stricture will give the greatest difficulty in diagnosis, even when the parts are exposed. In both, enlarged glands are found. The tuberculous glands are hard and cheesy. The carcinomatous area will have dilated and tortuous blood-vessels underneath the peritoneum; it also shows no scars of cicatization and is not so densely adherent in the early stages as the tuberculous variety. Maylard speaks of oedema and inflammation in the vicinity of the umbilicus as an indication of ulcerative tuberculosis, and Tillmanns remarks on the frequency with which chronic indurations of the abdominal wall, with slow formation of abscess, are followed by fistulas communicating with the bowel.

In Senn's monograph, previously referred to, will be found a differential diagnosis worthy of the most careful study.
The indications for treatment may be divided into two classes: First, for the tuberculous process itself, and, second, for the relief of mechanical interference with intestinal action, the result of cicatrization. The management of localized intestinal tuberculosis without obstruction is certainly surgical; but to what extent should the operation be carried?

Clinical experience has demonstrated that nearly all forms of primary tuberculosis in the abdomen may be cured by simple incision of the peritoneum, and many cases of tuberculous intestinal disease relieved in this way have been placed on record.

It is possible that the "malignant tumors" in the abdomen cured by laparotomy, recorded by Tait and others, may have been tuberculous.

Removal of the cecum and ileo-cecal coil or ascending colon has been practised with good results, and many cases are now recorded by Senn, Pilcher, Ochsner, Koerte, Sachs, and others. In most cases extensive regional glandular infection will be found. The appendix is frequently the starting point of disease, and has often been removed, leaving the tuberculous cecum and caseating glands untouched, and yet apparent cure has resulted. Each case must be judged on its own merits.

Strictures following upon the healing process and causing mechanical obstruction of the bowels belong to the radical operations of necessity.

Intestinal resection or extirpation of the ileo-cecal coil is most frequently demanded. Occasionally the extent of the involved area or the debilitated condition of the patient may render intestinal anastomosis above and below the obstruction the safer procedure. This is particularly the case in extensive disease of the ileo-cecal coil, rendering ileo-colostomy the operation of choice. Senn notes in this connection that even a short length of remaining large bowel is sufficient to dry the stool, and this was our experience in Case IV, in which the patient was operated upon by Dr. C. H. Mayo; also in a second case of ileo-colostomy for the relief of ileo-vaginal fistula, reported in the "Annals of Surgery" for November, 1897.

In other cases the adhesions of coils of bowel to the peritoneal plaque covering an intestinal ulcer may lead to angulation. In two of our cases this condition alone seemed to account for the obstruction. On separating these points of union we have noticed that the adhesions were thick and more vascular than in the ordinary inflammatory disease as encountered in the pelvis, and there were no planes of cleavage discoverable. There was also a structural change involving all the coats of the bowel at one limited point of contact. On separation, the affected parts had an eroded granular appearance, looking like a lupus of the skin after removing an adherent scar.

All these places should be either cleanly excised or turned into the bowel and carefully sutured in this position, as a point in the centre usually communicates with the intestinal lumen.

If the suture is secure and there is no need of gauze protection against possible leakage, silk should be used for that purpose, but if it seems desirable to quarantine the suspicious area, catgut should be employed as a suture material. In our experience the tract established by the gauze is almost certain to become infected with pyogenic organisms, and silk at the bottom of a tuberculous sinus means chronic suppuration, and a fistula having a communication with the bowel will ultimately form.

Drainage of primary wound secretion in the abdomen is seldom necessary in chronic disease, and usually does not take place even if desired, but occasionally a suspicious point should be isolated and connected with the surface by the formation of adhesions around a piece of gauze, to protect against infection or leakage.

Such treatment leaves much to be desired. The post-operative suppuration in Cases IV and V was of a peculiar oily character, very fetid, with, eventually, a minute fecal fistula; both of these patients had a considerable elevation of temperature while the discharge lasted.

If catgut has been used, the fistula will heal spontaneously in from three to twelve weeks, according to its extent; at least, this has been our experience.

In Case III there was no protection. While no post-mortem was secured, I believe there was a leakage at the suture line.

Intractable tuberculous ulceration of the sigmoid, either with or without stricture, has been successfully treated by a temporary or permanent inguinal colostomy.

In looking back over our experience in this class of cases we note their wonderful ability to withstand operative interference. The chronic nature of the disease seems to furnish a partial immunity to injury and operations can be fearlessly undertaken which would be unjustifiable in acute infections or cancer. The operations performed in several of these cases were very incomplete and unsatisfactory, yet apparent cure resulted.

Case I. Localized Tuberculosis of Ileum; Separation of Adherent Intestinal Coils; Secondary Operation for Fecal Fistula; Recovery.—Miss M. K., single, aged twenty-three years; American; Westfield, Minnesota. Admitted to St. Mary's Hospital, July 8, 1891, with a history of abdominal swelling and pain of a colicky character, which had begun rather suddenly a year previous. Constipation alternating with diarrhea and occasional attacks of vomiting were prominent symptoms. Menstruation prolonged and excessive, bladder irritable. There had been a progressive loss of weight and strength. Family history negative. Examination of heart, lungs, and urine negative; temperature, 100° F.; pulse, 100; abdomen tympanitic; muscles rigid and in places boardlike; uterus fixed by masses of a rather peculiar character in the small pelvis. This local condition on several examinations on different days never appeared twice just alike.
A diagnosis of pelvic peritonitis, probably of tubal origin, was made, and on July 12th the abdomen was opened in the middle line; the peritoneum was very thick and the omentum generally adherent; there was no fluid, and the intestines in the small pelvis were more or less covered with adhesions, and had formed the mass felt on vaginal examination.

In the vicinity of the umbilicus the small bowels were matted together, forming a partial obstruction. On separating these adhesions a coil of ileum was found to have a large, thick cicatrix on its free surface, and itself obstructive, but to which the neighboring intestinal coils had become adherent. The adjacent peritoneum was studded with tubercles. A small drain was inserted and the abdomen closed.

On the sixth day the abdominal wound opened and began discharging the contents of the upper small bowel, the escape of food taking place within a few minutes of its ingestion. The prostration became extreme. Three weeks after the first operation a finger introduced into the fistula showed a sharp spur in the bowel at the angle of adhesion; this spur was caught with a pair of forceps, one jaw in the afferent and one in the efferent portion of the bowel, and clamped (method of Dupuytren). Five days later the forceps cut its way through, and after a trying time during the next three months the wound healed. The patient completely recovered, and now, seven years and a half later, is in excellent health.

Case II. Tuberculous Ulceration of Ileum causing Obstruction; Intestinal Resection; Recovery.—C. K., a man, aged eighteen years; German; Janesville, Minnesota. Admitted to St. Mary's Hospital October 8, 1896. Five months previously he had been suddenly seized with vomiting and pain in the hypogastrum. The abdomen became bloated and bowel movements could not be secured for a number of days. There had been some urinary distress. After three weeks he improved and was able to be about, but the colic and distress were almost constant; movements from the bowels were exceedingly hard to obtain, and gave only temporary relief. There was a gradual loss of seventy pounds in weight; nausea was constant, and vomiting of daily occurrence. Family history good.

Examination.—Emaciation extreme; pulse, 130; temperature slightly subnormal. Urine contained a tenth of one per cent. of albumin, and indican in abundance. Heart and lungs normal. Abdomen greatly distended, and the dilated coils of intestines could be plainly seen during peristalsis. No tumor could be discovered.

Diagnosis, chronic obstruction of the small bowel. Operation, October 9th. On opening the abdomen, coils of the greatly distended small bowel protruded and were allowed to remain outside under hot towels in sufficient quantity to expose the seat of trouble, which consisted of an adherent mass of ileum near the ileo-cecal junction. In attempting to separate the adhesions and relieve the obstruction the distended bowel was opened and at once emptied and sutured. A large ulcerated and partially cicatrized surface was finally disclosed in the ileum, and this communicated with two coils of bowel by fistulous openings. In attempting to liberate this portion of bowel it was torn, completely through. Four inches of the ileum, including the diseased area, were excised and an end-to-end suture anastomosis effected. This was rendered very laborious on account of the inability to bring the parts to the surface, and the great disparity in size and thickness of the muscular coats of the two parts of the bowel united, the proximal portion being greatly dilated and much thickened.

The fistulous openings in the adherent coils were excised and the defects closed by purse-string sutures. A gauze drain was inserted. On removing the drain on the fifth day a small fascial fistula developed, which spontaneously closed in fourteen days.

Discharged November 14th in good condition. Now, two years and a half after the operation, he is in perfect health, and has gained a hundred pounds in weight. The pathological specimen showed the characteristics of tuberculous ulceration.

Case III. Localized Tuberculosis of Sigmoid and Tubo-ovarian Disease; Secondary Involvement of Ileum and Bladder; Operation; Death.—Mrs. F. H., aged thirty-six years; American; married; no children; Kasota, Minnesota. Admitted to St. Mary's Hospital April 29, 1897, with a history of pelvic pain extending over a period of six years. Bowels obstinately constipated. Bladder irritable. Menstruation excessive and lasting from ten to fourteen days. Digestion poor, colics frequent. Family history of tuberculosis and cancer.

Physical Examination.—Patient fairly well nourished. Heart and lungs normal. Urine contains a few pus corpuscles. Pulse, 96; temperature, 98.4° F. Abdominal muscles rigid. Uterus retroverted and adherent. An indefinite painful swelling can be plainly felt on each side of the uterus.

Diagnosis, inflammatory disease of tubes and ovaries.

Operation on May 1, 1897. A coil of lower ileum and the bladder adherent to the sigmoid. There were no planes of cleavage, such as are usually found in inflammatory disease. The tissues were friable and looked granular when separated. Both the bladder and ileum were opened during separation and the injuries at once were carefully sutured. An irregular ulceration of sigmoid, partially cicatrized, was drawn to the surface turned in, and the peritoneum sutured over. The ovaries and tubes were bound down by dense adhesions, and both tubes contained straw-colored fluid. The appendages were removed and the uterus suspended anteriorly. The abdomen was closed without drainage. Death occurred on the fifth day from septic peritonitis. There was no post-mortem.

Case IV. Tuberculosis of Cæcum and Appendix; Operation; Improvement; Readmitted Seven Months Later with Obstruction of the Bowels; Ileo-colostomy; Recovery.—Mrs. H. O., aged thirty-seven years; American; New Richland, Minnesota. Married and the mother of nine children, the youngest of whom is three years old. She has not been well since the birth of the last child, has been weak and tired, and hardly able to do her work.

For the past six months has had a constant pain in the right side and has suffered from cramps in the bowels; constipation alternating with diarrhea and occasional discharge of a slimy character has been observed. There has been some irritation of the bladder, quite annoying at times. Menstruation normal. Patient also states that there is an enlargement in the right side which, she thinks, has been present for three years, and is increasing in size. Family history good.

Physical Examination.—The patient is of an anemic appearance. Temperature, 99.5° F; pulse, 100. No evidence of disease in the lungs. Heart normal. Urine contains pus corpuscles. An indefinite thickening in the region of the right broad ligament can be felt through the vagina and rectum. In the right side of the
abdomen is a well-marked enlargement occupying the position of the cecum and extending upward to the lower free ribs. It is irregular in outline and appears to contain gas. Diagnosis, probable carcinoma of the cecum.

Operation on April 28th. A free incision was made directly over the enlargement, which was found to be the cecum. It was adherent and the surface was marked with boardlike scars. The appendix was thoroughly involved and lay in the pocket under the ileo-rectal junction. The right ovary and tube were also involved in the caseating mass. Lymphatic glands in the neighborhood were enlarged and cheesy. A portion of the cecum was excised with the appendix and right ovary and tube. A retrocecal tuberculous pocket was curetted and iodoformized, and an iodoform gauze drain was inserted. On its removal a small fecal fistula appeared. For six weeks an oily offensive discharge continued, and a continuous temperature elevation was noted. Patient was discharged with a cicatized wound June 8th.

In September the patient was reexamined and appeared to be in excellent health, having gained thirty-three pounds in weight, but she complained of some stomach disturbance, with attacks of vomiting and obstinate constipation, which have appeared within two weeks.

November 7th.—The patient was readmitted to the hospital suffering from obstruction of the bowels, which had lasted nearly a week; vomiting was frequent and the abdomen was markedly tympanitic. It appeared that the symptoms of obstruction had been steadily increasing since the examination in September, and were relieved with more and more difficulty until the trouble had culminated in the present attack. It was also noted that the bladder had become involved, and shortly before an abscess had opened into this viscus and still discharged by this route, to her great distress.

Operation by Dr. C. H. Mayo. The ileo-cecal coil was involved in a tuberculous process producing the obstruction. An indurated area connected with the bladder and this extensive disease was not disturbed. The ileum was divided eight inches above the ileo-cecal valve at a point well above the disease, and the distal portion was emptied and the cut end turned in and sutured. The proximal end of the ileum was anastomosed with the transverse colon by a Murphy button.

The contents of the enormously distended small bowel were milked through the button into the colon. The abdomen was closed without drainage. The bowels acted freely within a few hours and the patient rapidly convalesced. The discharge of pus and tuberculous débris through the bladder immediately lessened, and in four weeks entirely disappeared. The button came away in twelve days. Patient was discharged December 15th in good condition. The ultimate result would seem to be uncertain.

Case V. Tuberculosis of Cæcum and Ascending Colon; Formation of Tuberculous Abscess; Operation; Improvement.—Mrs. F. A. G., aged thirty-seven years; American; Le Roy, Minnesota. Admitted to St. Mary’s Hospital September 27, 1898. Has been married two years, and is the mother of one child, two months old. She has been unable to nurse her child. Menses have not reappeared as yet. She states that for two or three years she has been annoyed by a pain in her right side, which was exacerbated by the pregnancy.

After confinement, her physician, Dr. McMillet, of Le Roy, discovered a tumor in the right side of the abdo-

men, which has been exceedingly tender. Bowels irregular, of late a tendency to diarrhea. Family history of tuberculosis.

Physical Examination.—A spare woman of anaemic appearance. Heart and lungs normal. Urine negative. Temperature, 101° F.; pulse, 110; generative organs normal. There is an oblong mass in the right side occupying the usual situation of the cæcum and ascending colon, which feels hard and nodular; it evidently contains gas. In the loin there is a tendency to induration which may be due to a deep-seated abscess. Leucocytosis not present. Diagnosis, tuberculosis of cæcum with secondary abscess.

Operation on October 1, 1898. A lateral incision was made with its centre over the inflamed area. On opening the abdomen, the walls of the cæcum and ascending colon were found to be enormously thickened, and in places, ulcerated patches, well roofed in by thick plastic deposit, could be made out.

The deep glands behind were caseated. The inflammatory deposit was a typical tuberculous abscess, adherent to the abdominal wall and communicating with the colon, into which it evidently discharged. The colon was opened and extensive tuberculous ulceration could be seen. So far as could be demonstrated, the disease was confined to this region. The abscess cavity was iodoformized and packed with gauze, and the opening in the bowel repaired and covered with an omental graft. A slight facial fistula followed the removal of the gauze drain on the fourth day, and for six weeks a foetid oily discharge continued.

During this time the patient constantly had high temperature. Discharged from the hospital November 8th, greatly improved in health. Now, four months after the operation, the mass is very much less prominent, and there is a gain of thirty pounds in weight, and a corresponding improvement in general health can be noted.

Case VI. Tuberculosis of Sigmoid, causing Stricture; Operation for Obstruction of the Bowels; Recovery.—Mrs. J. A. W., aged thirty-four years; Lime Springs, Iowa. Admitted to St. Mary’s Hospital June 27, 1898. Patient has been married two years; no children. She has had three well-marked attacks of appendicitis, and at this time is just recovering from the fourth attack. Her physician, Dr. J. W. Reed, of Lime Springs, states that the character of the trouble appears to have changed, the earlier attacks being typical, while the illness from which she is now convalescing has been in the nature of an obstruction of the bowels. Menses regular, bowels generally constipated. Family history good.

Physical Examination.—Patient of delicate physique. Temperature and pulse normal. No evidences of disease of lungs, heart, kidney, or generative organs. Palpation of the appendix elicited some complaints of pain.

A diagnosis of relapsing appendicitis was made on the history. On June 26th the diseased organ was removed through a short lateral incision. The appendix was adherent and contained several strictures. There were no signs of recent inflammation. Discharged July 15th.

Within one week of her arrival home she experienced another attack precisely like the last one. The obstruction was never fully relieved from that time. The vomiting, intense pain, and abdominal distention yielded only after great effort to act upon the bowels, and the re-

 Relief afforded was very temporary. It was noted in this later history that only small enemata could be retained, although nothing could be felt by digital examination through the rectum.

Patient readmitted October 15th in bad condition. Pulse rapid and feeble. Abdomen greatly distended with gas, peristalsis being markedly visible. This was especially noticeable in the left iliac region. Emaciation extreme. No action of the bowels had taken place for two weeks; once flatus had escaped. The vomiting was almost constant, and the pain could be checked only by the subcutaneous exhibition of morphine.

Operation was performed as soon as the patient could be prepared. A median incision revealed a tangled mass of bowel in the pelvis. This proved to be two coils of ileum adherent to a point on the sigmoid within two inches of the beginning of the rectum. The separation was difficult and resulted in opening each loop of the small bowel. The adhesions were not general, but rather a dense union over a small area, being friable and granular. The surfaces containing the defects in the intestinal wall were turned into the lumen of the bowel by sutures. The disease in the sigmoid seemed to completely surround the gut, and it could not be brought to the surface. An assistant placed two fingers in the rectum and I was able to depress the structure sufficiently to invaginate it into the rectum, while my assistant forced his fingers through and dilated it thoroughly. In doing this, the friable tissues ruptured. This was repaired as well as time would allow by transverse suturing, which enlarged the opening, and the result was far from being satisfactory. The pelvic peritoneum was studded with tubercles.

A large iodoform-gauze tampon was placed to protect against the expected leakage. The sigmoid was brought to the surface and fastened to the upper end of the wound above the drainage, and marked with black silk guides, and finally the ileum proximal to the sutured parts was fastened along the side of the sigmoid to the peritoneal edge of the wound, and also marked with silk guides, to be used should it be necessary later to open the bowel to relieve the obstruction.

Patient in collapse, from which she but slowly recovered. The obstruction was not relieved, and the condition appeared to be hopeless. In forty-eight hours the sigmoid was opened, but without relief: twelve hours later, although the patient was barely alive, the small bowel was opened and some gas and liquid contents began to escape.

From this time on the discharge of small-bowel contents became profuse, and after a prolonged struggle the patient rallied. The fistulous openings healed spontaneously. The stricture below can now be reached by the fingers in the rectum and is stretched digitally twice a week. The patient is gaining rapidly in weight and strength. Discharged January 8, 1899.

Case VII. Tuberculosis of the Cecum and Appendix: Appendectomy; Improvement.—Miss A. E. B., German, aged eighteen years; Elma, Iowa. Admitted to St. Mary's Hospital November 28, 1898. The following history was obtained: Attacks of abdominal pain began about eight months ago. These spells have grown more severe and are accompanied by diarrhea. From the first the looseness of the bowels has been marked, and the discharges are slimy and offensive in character. There has been some urinary irritation at times. Menses stopped five months ago. The weakness has been progressive and she has lost thirty-five pounds in weight.

There has been a more or less constant soreness in the right side. Family history good.

Examination.—A slender, anæmic girl, with a pulse of 116 and temperature 101° F. Lungs, heart, kidneys, and generative organs show no evidences of disease. Abdomen tympanitic, and considerable gurgling can be developed in the colon. The region of the cecum is board-like and the lower right rectus muscle is fixed.

An indefinite enlargement at this point can be mapped out, which contains air and fluid. Examination of stools for bacilli of tuberculosis negative. Diagnosis, tuberculosis of cecum and ascending colon.

Operation on November 30th. Cecum adherent and greatly thickened; on releasing the adhesions, white, board-like scars can be seen.

The appendix was of large size and cheesy, breaking off close to the cecum while enucleating it. The deep glands were of considerable size and extended in a chain upward as far as could be reached. A gland was removed and found caseating. The omentum was converted into a ropelike mass and was adherent to the diseased area. The stump of the appendix was cut out of the cecum, and the defect closed by suture.

The parts were iodoformized and the incision was closed without drainage. The diarrhea was checked, and has not yet returned. The patient has gained in weight and strength, but the ultimate result is in doubt. Discharged December 29, 1898.

HOW FAR IS RETROVERSION OF THE UTERUS RESPONSIBLE FOR SOME OF THE FUNCTIONAL NEUROSES?

By MIRIAM GARDNER, M.D., Clifton Springs, N. Y.

I wish to call attention to this subject, which has been of especial interest to me during the past few months in my practice, as I have watched the neurasthenic and hysterical patients who have come under my care with retroversion of the uterus.

I speak of this form of displacement as it is the one I have always found, if any, in these patients, and I shall confine myself to that class where there is simply retroversion, uncomplicated by adhesions, congestion, or inflammation.

To what extent, if any, is such a displacement the cause of a patient's nervous unbalance? From the histories given, I have decided that in each case the loss of control over the production of nerve power and exhaustion of nerve centres have not been due to the displacement of the uterus, but to other causes quite independent of this pelvic disorder. In several of these cases the anxious parent has brought her daughter for an examination, feeling that a thorough investigation of the rest of her body had not revealed sufficient trouble to account for the nervous symptoms.

Upon examining some I have found no retroversion; in others, suffering from dysmenorrhoea and pain in the lower part of the back, there has been a retroverted uterus, and upon correcting the displacement the patient has improved in health; but her habit of life and
character were fixed, and she only reached out to find other reasons for nervous feelings, meanwhile allowing her mind to dwell upon the pelvic disturbance from which she was relieved.

In other cases, where no symptoms given pointed to retroversion, the uterus was badly retroverted. One greatly overindulged patient of nervous temperament, the mother of six children, was always usually well until four years ago, when her only daughter died suddenly, and the shock was too great a strain upon her nervous system, and since that time she has been extremely hysterical.

She had no symptoms which would point to pelvic trouble, but, upon examination, I found the uterus retroverted, probably caused in this case by constipation, and lying almost constantly upon her back. If retroversion is the cause of these nervous disorders, why do some extremely nervous patients have retroversion, and others, free from nervous symptoms, have the displacement?

Those who understand the anatomy of the pelvic organs know they are normally located securely enough not to be easily shaken out of position in any person in comfortable health, that it would take a severe jar or fall to get the uterus greatly out of place, especially backward, and that constipation, from which most nervous patients suffer, is one of the chief causes of retroversion, the constant backward pressure upon the uterus causing stretching of the round ligaments; thus the organ is changed from its normal position and the signs of muscular relaxation are present, as well as relaxation of the tissues of all of the internal viscera.

Upon closely questioning I have found that the fond parents, in their mistaken kindness, are unconsciously largely responsible for the nervous conditions. When children the patients were never taught to know the meaning of cheerful, prompt obedience; selfishness was unconsciously cultivated, and grew rapidly with the years; the health was not properly looked after, unsuitable food was allowed and taken at irregular hours, no systematic exercise was taken daily in the open air, and there were no regular hours for sleep. As the years went on they were allowed to read or study into the late hours of the night, when the body and mind demanded rest.

As young ladies, with many, snug corsets and high-heeled slippers were indulged in daily, and, as they were allowed to dance into the early morning hours, because it was "the thing" to do, the nervous system became gradually unbalanced, and with torpid liver, constipation, loss of appetite and sleep, and unnecessary worry under such high pressure and improper living, they were physically in a condition where any extra nervous strain developed hysterical symptoms or nervous prostration, and they were thus unfitted to be a blessing to themselves or others, for they ruled, not only the parents, but the entire household, all yielding to the patient's hysterical whims, rather than go through the exhausting strain of a nerve storm.

Parents should realize the great importance of teaching their children to faithfully look after their general health, and thus avoid the list of innumerable ills that follow one after another when the body is not properly cared for, thus causing functional neuroses.

With regular daily outdoor exercise, sufficient hours for rest, systematically daily emptying the bowels, eating wholesome food, drinking plenty of water, and wearing clothing that will not interfere with the circulation, the entire body will be healthfully nourished, and each person thus physically fitted to perform the duties of life. If this class of patients, when children, had been taught by the exemplary living of parents, as well as by precept, to meet their little trials and disappointments bravely, then as the years went on and more trying experiences appeared (which are sure to come sooner or later into every life) they would be prepared mentally as well as physically, with perfect self-control, to meet whatever came, instead of being left in a neurasthenic or hysterical condition, not being able to cheerfully accept the existing circumstances over which they or their parents often have no control.

While in some cases retroversion doubtless aggravates neuroses already existing, I do not think it is the primary cause of the nervous unbalance found in so many ungoverned, selfish, self-willed hysterical women, who are unfitted to be a blessing to the world, but often are unwisely selected as wives and mothers.

It must be borne in mind that all of the abdominal tissues, pelvic floor, abdominal walls, and even the mesentry attachments of the internal viscera, are alike weakened in these patients, and one can not be strengthened without all being naturally physically benefited.

Thus, whatever new symptoms may arise in these cases may be as justly referred to the relaxation and displacement of other internal viscera as to a retroverted uterus, and stomach difficulties and a movable kidney are often expressions of neurasthenia.

In the treatment of these cases I have realized how much faster these patients gain in health away from their homes under the systematic treatment for building up the general health, as given in a sanitarium. Here they realize the necessity of carrying out the doctor's orders, and with appropriate baths and general treatment, followed by rest, the system is again restored to a more normal condition, and pelvic troubles that at home seemed of the greatest importance they have learned were easily relieved. The local treatment may be varied according to the condition found. In many of these cases faradic electricity helps greatly in toning up the pelvic tissues. In the treatment every other day, one electrode is placed back of the uterus and the other over the abdomen for ten minutes, increasing the current strength as the patient can bear it. When the backward displacement is slight, it is better to give no
local treatment, but have the patient morning and evening take the knee-chest position from five to ten minutes and avoid lying on her back. Deep breathing exercises and light gymnastics later on, when stronger, greatly aid in strengthening and giving proper tone to the abdominal and pelvic tissues. Following these out faithfully, and aided greatly by the general treatment, the uterus has in most cases in a few weeks assumed and retained its normal position.

In others, where the mind had become centred on the displacement as the cause of poor health, it has been found better to use the medicated cotton-wool tampon as a support for a few times, gradually making it smaller with each treatment until the patient can go without it without the slightest discomfort, and during that time becoming fully convinced that the displacement was corrected; then no pelvic support was needed.

In many cases too much stress is placed by the home physician upon the pelvic displacement, and too little attention given to building up the general health. With this reversed, the patient in most cases improves rapidly.

While in marked cases of retroversion local treatment is needed for weeks, in slight displacements it should be avoided as far as is justifiable. When improving the general health, taking faithfully special exercise with reference to the pelvic displacement, and following out the systematic line of hygienic treatment, the conditions will soon be corrected and the patient once more practically well.

While in this paper I have dwelt largely upon the hysterical type of neuroses, neurasthenia caused by nervous fatigue and manifested by eye strain, disturbances of circulation, digestion, and secretion bear an equally important place in the consideration of this subject.

Dr. F. X. Dereum, in his able paper upon The Relation of the Great Neuroses to Pelvic Disease, published in The American Gynaecological and Obstetrical Journal of August, 1898, makes the following statements:

"There is no necessary relation between neurasthenia and pelvic disease.

"There is no relation between pelvic disease and hysteria, even where the two affections coexist in the same case."

The Treatment of Yellow Fever.—According to the Brazil correspondent of the Medical Record for August 5th, Dr. George Butler, an American medical missionary, practising in the State of Pernambuco, has reported a large number of cases treated with small repeated doses of castor oil and turpentine, and says that he has not lost a case when the treatment was begun before the action of the kidneys became involved, and when yellow fever was not complicated by some other disease. His treatment is as follows: Three drops of turpentine in a teaspoonful of castor oil every hour for twelve hours, after which only once in two hours until the fever ceases.

A REPORT OF FOUR CASES OF EPIDEMIC CEREBRO-SPINAL MENINGITIS, WITH SPECIAL REFERENCE TO THE VALUE OF LUMBAR PUNCTURE AS A MEANS OF DIAGNOSIS.*

By JOSÉ L. HIRSH, A. B., M.D., BALTIMORE, DEMONSTRATOR OF ENTHROLOGY AND ASSISTANT TO THE PROFESSOR OF PEDIATRICS IN THE UNIVERSITY OF MARYLAND.

The subject of epidemic cerebro-spinal meningitis has been brought to the notice of this society so recently that I would hardly feel justified in calling your attention to it this evening were it not for the fact that the disease is not only on the increase among us, but in parts of this State and in many other States has assumed the proportions of a grave epidemic. The public-health reports show that during the week ending April 22, 1899, two cases and six deaths of cerebrospinal meningitis were reported in Baltimore. This by no means shows the true condition of affairs, as until recently this affection was not included in the list of diseases to be reported to the health department. In the city of Washington there have been sixty-four deaths from epidemic meningitis since January, 1899. A perusal of the health reports of other cities shows a similar increase of mortality in this disease. The mortality in various epidemics ranges from twenty to eighty per cent.

Again, while the etiology of this disease has received considerable study in this country as well as abroad, there is still some discussion as to the characteristics of the specific organism. I need merely call your attention to the differences in the description of Jaeger (1) and Heubner (2) on the one hand, and Weichselbaum (3) and Councilman (4) on the other. Pfauender (5), in a recent article, has pointed out that the specific causes of epidemic meningitis are diplococci of different though closely related varieties, which he has designated as groups A and B, whose characteristics are as follows:

Group A.

1. Diplocci, broad ends side to side.
2. Occasionally tetrads, seldom in chains.
3. Decolorized by Gram.
4. Little or no growth on agar.
5. No growth on bouillon, milk, or potato.

Group B.

1. Same.
2. Forms chains.
3. Not decolorized by Gram.
4. Luxuriant growth on agar.
5. Growth on bouillon, milk, and potato.
6. Poor growth on serum.

While Leichtenstein (6) first called attention to a diplococcus intracellularis in cases of meningitis, it was Weichselbaum who first gave a detailed description of the organism known as the "Diplococcus intracellularis meningitidis." He found the organism present in the meninges of the brain and cord of six cases. He isolated the organism and found it to be pathogenic to

* Read before the Clinical Society of Maryland, May, 1899.
mice and guinea-pigs, but as he could not regain the organism from the affected membranes, he hesitated to announce positively that the organism was specific for epidemic meningitis.

The next important addition to our knowledge on this subject was made by Jaeger, who studied an epidemic of meningitis in Stuttgart in 1895. He found the organism in a series of autopsies and distinguished it absolutely from the pneumococci, the only cocci with which it might be confounded. Heubner was able to corroborate on the living the results obtained by Jaeger at autopsy; by means of lumbar puncture he obtained the spinal fluid from six cases of meningitis. The microscopical examination showed the diplococci within the pus cells, and the inoculation of media gave the organisms in pure culture. The pathogenic powers of the organism were not marked, the only susceptible animal being a goat, which received a typical meningitis when the fluid taken directly from the spinal canal of an infant was injected into the subdural cavity of the animal. His description of the organism corresponds closely with that given by Jaeger.

Councilman has recently reported a hundred and eleven cases of epidemic cerebro-spinal meningitis occurring in and about Boston. In thirty-five of these cases on which post-mortem examinations were made, diplococci were found in cultures or on microscopic examination of exudates in all but four cases. In most of the cases they were found in cultures on microscopic examinations of exudates, and in sections. Lumbar puncture was performed in fifty-five cases; diplococci were found either on microscopic examination of the spinal fluid or in cultures in thirty-eight cases. In a certain number of cases cultures failed to give the organisms, although they were abundantly present both on cover-slip examination and in sections. As showing the difficulty in growing the organisms in cultures made from the meninges at the post-mortem examinations, ten cultures were made from one case from the exudation on the brain and six from the cord, cover-slip examinations showing abundant organisms in the cells. Only two of the cultures from the brain and one from the cord showed a growth, a single colony being found on each tube. In ten cultures from the brain and nine from the cord in another case, but two tubes, one from the brain and one from the cord, showed a growth.

The following cases of epidemic meningitis which have come under my observation, the spinal fluids of which were studied bacteriologically, may prove of interest:

**Case I.**—M. C., aged two years and six months, colored, was brought to the dispensary of the University Hospital on April 9, 1899. From the mother the following history was obtained: Family history negative. Child was normally born and fed on the breast up to the tenth month. Began teething at seven months and walking at fifteen months. Had measles when one year old; otherwise none of the diseases of childhood.

About two weeks ago (March 25th) the child fell and struck its head against a chair; was slightly stunned, but soon recovered its normal condition. Three days later (March 28th) the child was taken suddenly with vomiting, headache, epigastric pains, and fever, and later on the same day with a severe convulsion; neither the vomiting nor the convulsion was again repeated. The child's condition became progressively worse until about seven days later, when the following note was made:

**Clinical Diagnosis.**—Cerebro-spinal meningitis; broncho-pneumonia.

April 10th.—Condition unaltered; if anything, worse. A lumbar puncture was now made and about fifty cubic centimetres of a cloudy fluid were withdrawn. The fluid flowed very rapidly at first, and then drop by drop, the whole quantity being obtained in about ten minutes. Immediately following the operation the child showed symptoms of improvement; the neck muscles were less rigid, and it was more easily aroused.

11th.—The mother states that yesterday afternoon, about 5 p.m. (five hours after puncture), the child called for water, the first time within a week. Patient is markedly better. Head can be brought forward; patient sits up and appears to notice the surroundings. Temperature, 101° F. Bowels constipated. Urine normal. Examination of blood shows a leucocytosis.

12th to 15th.—Continues to improve. Lungs clearer.

27th.—Child has completely recovered.

*For a copy of the clinical history of this case I am indebted to Dr. Mary E. Osmond.*

**Case II.**—S. H., aged eight years, colored. Family history good. No injury. Child had been in usual health, and attended school on December 22, 1898. During the night was taken ill with vomiting, epistaxis, and severe pains in the head. On the evening of December 23d the patient had a severe chill, which lasted for an hour; this was followed by convulsion, fever, and delirium. At this time it was observed that the body became rigid, the head being drawn backward. On December 29th there was another spasm; from this time to January 9, 1899, when the case was first seen, it was said that the body had been stiff; there was constant pain in the head, neck, and back.

On January 9th examination showed the body in a state of opisthotonus, the head being drawn back be-
tween the shoulder blades, the muscles of the neck and back tense and hard; legs drawn backward, but could be slightly moved; the arms unaffected. Marked tenderness along the spine. No herpes or rash was noted. Abdomen distended; no splenic enlargement. Bowels confined; enuresis. Temperature, 98° F.; pulse, 102. Blood tested for typhoid reaction; negative. Marked leukocytosis. On January 12th a lumbar puncture was made by Dr. Stokes. His report is as follows: Withdrawn by a sterile needle a few drops of cloudy fluid, which were put into a tube of glycerin-agar, and in twenty-four hours showed a number of fine pin-point colonies, which consisted of diplococci, staining with aniline dyes, decolorizing by Gram. Bacteriological diagnosis: "Diplococcus intracellularis meningitidis." January 11th to 13th.—Condition unaltered.

16th.—Severe pain in right ear.

22d.—Patient was able to take a small amount of liquid nourishment; a slight movement of the head observed. The improvement was gradual from this time. Repeated urinary examinations with negative result.

April 21, 1899.—The boy has entirely recovered, and has been attending school for the past two weeks.

Case III.—For the opportunity of seeing this and the following case I am indebted to Dr. J. T. McCarthy.

Blanche T., colored, aged four years. Family history negative. Child had pneumonia at ten months, otherwise none of the diseases of childhood. Patient was taken suddenly, while at play, with pains in the legs and back, followed the next day by headache, vomiting, and high fever. Child was seen one week later, when its condition was as follows: Marked opisthotonos, muscles of neck, spine, and lower extremities rigid; marked hyperaesthesia along the spine; convergent strabismus, pupils irregular and dilated, no reaction to light; child comatose, and with difficulty aroused. No herpes, but an eruption of fine purpuric spots covered the entire body. Ankle joints swollen and painful. Bowels constipated. Pulse rapid and irregular. Temperature normal. A lumbar puncture was made and about ten cubic centimetres of a cloudy fluid were obtained. The bacteriological examination of the fluid will be mentioned along with the other cases.

One week after puncture the child’s condition was much improved; the mother said the improvement was noticeable the day after the puncture. When I saw the child yesterday she was in perfect health and playing about the house.

Case IV.—Joseph A., white, aged five years, I saw for the first time yesterday (May 3, 1899), and obtained the following history: Child has been sick and under the care of his physician for the past seven weeks. Patient was taken with headache and pains in the limbs on March 13, 1899, followed the next day by severe vomiting and convulsions. He has been confined to bed since this time. At present patient is in bed, lying flat on his back, with head drawn back so far that his forehead is partly concealed by his pillow; eyes are fixed and mouth wide open; ecniation is extreme. Can be aroused with difficulty. It is impossible to bring the head forward. The slightest attempt to do so causes the child to cry out on account of pain. There is marked tenderness along the whole spine. The muscles of the leg are rigid. The pupils are widely dilated, the right more than the left. Hearing not impaired. There is incontinence of faces and urine. Pulse rapid; temperature, 99° F.

Lumbar puncture was made between the third and fourth lumbar vertebrae, and with a sterile hypodermic needle about fifteen cubic centimetres of an opalescent-looking fluid were withdrawn.

May 5, 1899.—Child’s condition continues the same to-day. He rallied somewhat yesterday afternoon after the puncture, but soon lapsed into a semicomatose condition.

Bacteriology.—The fluid obtained from Case I, about fifty cubic centimetres in quantity, was decidedly cloudy, and on chemical examination showed a small amount of albumin. Microscopical examination showed many pus cells, chiefly polymuclear leukocytes; many of the cells contained diplococci, varying in number from two to twenty or more. The two cocci are situated with the broad sides together, closely resembling the gonococcus. They stain with the usual aniline dyes, and decolorize by Gram’s method of staining. Cultures were made by allowing the fluid to drop directly from the spinal canal, through the sterilized puncture needle, into the glycerin-agar and blood-serum tubes. From one to three cubic centimetres of the fluid were added to each tube. Of twelve glycerin-agar and eight blood-serum tubes so inoculated, after twenty-four hours’ incubation, only three glycerin-agar and three blood-serum tubes showed any evidence of growth. The growth on glycerin agar showed minute round, whitish, sharply defined, non-confluent colonies, which microscopically consist of typical diplococci, staining with aniline dyes, and decolorizing by Gram. After several transplantations the organisms seemed to thrive better, but died out in about two weeks; the blood-serum cultures remained viable longer than those on glycerin agar, and was the best medium for its growth; while the colonies were at first isolated, older cultures on the serum gave a continuous and fairly luxuriant growth. The blood serum is not liquefied. No growth occurred on plain agar, on gelatin, or on potato. Likewise there was no change in litmus milk. Bouillon was slightly clouded, with a small amount of sediment. The twenty-four-hour bouillon cultures, when injected subcutaneously into rabbits and mice, were without any effect, similar cultures injected intraperitoneally were mildly pathogenic. Of three rabbits injected intraperitoneally, one died after three days; no post-mortem. Of two white mice so injected, one died after twenty-four hours, and on post-mortem the organism was recovered.

The microscopical and bacteriological findings of Cases II and III were in every way similar to Case I, although no animal experiments were made.

The fluid from Case IV was cloudy and contained small shreds of fibrin; chemically examined by Heller’s method, it showed a very definite ring of albumin.

Microscopically there were a few large epithelioid cells and many pus cells, but no diplococci could be found within the latter. Cultures were made as in Case I. After twenty-four hours one tube of glycerin-
A faint trace of albumin is always found in the normal cerebro-spinal fluid. In my cases of meningitis the amount of albumin was decidedly increased; however, no quantitative estimation was made. The amount of albumin present in the normal fluid is variously estimated from 0.01 to 0.04 per cent.; in meningitis it may be increased to 0.3 to 0.5 per cent.

As to the therapeutic value of lumbar puncture all do not agree. In Case I improvement followed so immediately upon the operation that I feel justified in concluding "post hoc, propter hoc." In Cases III and IV there was at least a temporary improvement following the operation. By relieving abnormal pressure, and probably by getting rid of some of the toxins, the beneficial results can readily be conceived. The technique of the operation is simple and the pain to the patient is but slight. In children I have found the best position to be with the child lying on its right side and its back slightly arched, so that the spine processes stand out prominently. Many prefer the child in the sitting position. The puncture is to be made between the second and third, or the third and fourth, lumbar vertebrae. The needle, from five to eight centimetres long, is thrust in about one to two millimetres from the median line, so as to avoid the strong intraspinal ligament. When the needle is within the spinal canal its point can be felt to move freely; if the fluid does not flow spontaneously, slight suction may be made with a hypodermic syringe. Needless to add that all antiseptic precautions must be observed.

A procedure so simple, so readily carried out, and so absolutely devoid of danger, has, I think, no contraindications for diagnostic, if not for therapeutical purposes.

ABDOMINAL INJURIES DUE TO BLUNT FORCE. REPORT OF TWO CASES*  

By RUSSELL S. FOWLER, M.D., 
ATTENDING SURGEON TO THE BROOKLYN HOSPITAL HISTORIANS; 
ADJUTANT SURGEON TO THE METHODES KIPCHOFF HOSPITAL; 
CONSULTING SURGEON TO THE SOUTHERN DISPENSARY AND HOSPITAL, ETC. 

Case I.—John F. L., twenty-two years of age, was admitted to the Brooklyn Hospital, service of Dr. George Ryerson Fowler, September 29, 1897. 

History of Disease.—On the day previous to that on which he was taken ill the patient had been deeply intoxicated. He gave an ambiguous account of an accident, the nature of which he was unconscious. The attack began September 25th with general abdominal discomfort and pain, which was most marked in the right iliac fossa. Vomiting occurred twice; character, stomach contents. Onset sudden. Bowels moved on day of attack and on following day. 

Present Condition.—Moderate tympanites. General abdominal pain and tenderness. Point of maximum tenderness over suprapubic site of appendix in right iliac fossa. Stomach does not retain food. Bowels moved. Gas passed. Both recti rigid, right more rigid than left. Temperature, 101° F.; pulse, 124; respiration, 28. A diagnosis of appendicitis was made and immediate operation advised. As the patient was being anesthetized, a friend of his who had been driving with him the evening before the attack sent word that the patient had suffered a severe injury by reason of the horse starting suddenly as they were about to enter the carriage, the wheel striking the patient in the abdomen. It was not until the effects of the alcohol had worn off that the pain had been felt. This threw the diagnosis of appendicitis in doubt, and a diagnosis of a right-sided intra-abdominal lesion due to traumatism was substituted. 

Operation.—Right rectus laparotomy. As soon as the peritoneum was entered fluid blood and clots escaped. Intestinal coils and peritoneum were everywhere moderately congested. Right half of abdomen was explored for site of hemorrhage. Median incision. Lesion found to be a rupture of the mesentery of the ileum to the left of the median line. Iodoform-gauze packing. Wicking drains through both wounds. Wounds partially sutured. Uneventful recovery. Discharged November 3, 1897. 

Previous History.—On Sunday, day before admission, patient was seen at his home by myself. This was at 2 p.m. Two hours previous to my visit the patient, while in the erect position, was kicked by a cart horse. The site of injury was over the middle line, below the umbilicus, and extending more to the right side than to the left. The direction of the force from the account of the accident was backward, and of sufficient power to cause slight superficial redness and a moderate beginning hematoma at the border of the right rectus and lying in front of it. The abdominal wall at the time of injury was relaxed. There was no rupture of the rectus. There was a thick layer of fat present. The kick had been received previous to dinner, and the rectum and bladder had been emptied shortly before. There had been no previous abdominal trouble of any kind. Vomiting had occurred twice, once directly following the injury, and again within the hour. Bile was present in each case. Pain had been severe at first, but now was gradually receding. Tenderness was present over a limited area represented by the superficial redness. Pulse, 100; temperature, 99° F.; respiration, 22. The family physician had ordered morphone sulphone, an eighth of a grain every three hours. The patient had taken one of these just before my arrival. There was no shock present, and but very slight distention, if any. There was very slight dulness over the right flank as compared with the left. The right leg was extended and the left drawn up. There was no bulging at any of the hermal rings. No gas or urine had been passed since the accident, nor was there any desire so to do. Inasmuch as I had been called in an emergency, owing to difficulty in getting their family physician, I could not take charge of the case, though I was made known to the family, as I had taken care of one of the sons on a previous occasion. I told the family that there was a possibility of some trouble within the abdomen, and advised them to have their physician see the case again. At 5 p.m. I was again called. I found the patient’s abdomen distended, but not to a marked degree. Pulse, 120; temperature, 100.6° F.; respiration, 32. No gas or urine had been passed. Considerable gas had been belched up. Vomiting had occurred twice or thrice since my first visit. Its character was the same as at first. There was no shock present. No rigidity of rectus. Belly soft. Slight dullness over right flank. Pupils slightly contracted. Another morphine pellet had been taken thirty minutes before my arrival. There was a slight suggestion of the abdominal facies. Tenderness and pain were more marked. There was a continuance and increase of all the symptoms. The bladder could be felt as a rounded mass projecting above the pelvis. I advised immediate removal to the hospital, and told the family that a grave internal injury was present. They consented, but later notified me that they wished a consultation. I arranged for a consultation between the family physician and Dr. George Ryerson Fowler at 7.45 p.m. The patient had taken more morphine and the symptoms were at a standstill. Urine was passed voluntarily. From some outside source the people were prejudiced against entering a hospital, but finally consented to have the patient taken there in the morning. However, the patient did not arrive at the hospital until the afternoon of the day following the injury. His condition on entering the hospital was bad. Pulse, 140; temperature, 100.5° F.; respiration, 32. Slight face; bluish-gray clammy skin, cold extremities. Not much pain. Slight tenderness. Considerable disention. Operation twenty-eight hours and a half following injury. Abdominal cavity opened in median line. Large amount of fluid blood, bloody serum, flakes of exudate, and a few partially broken-up clots sponged away. Severe peritonitis was present. Intestines intensely congested and covered in places with fibrin exudate. Almost the first loop of small intestine examined showed a circular opening the size of a silver half dollar. This was on the convex surface of the gut farthest from the mesentery and within twenty-eight inches of the ileo-cecal junction. The mucous membrane was everted and the opening filled with a clot.

* Read before the Brooklyn Pathological Society, April 13, 1899.
which in conjunction with friable adhesions to a neighboring coil shut off the interior of the bowel from the general peritoneal cavity, and in addition caused an angulation at that point. This opening was protected. No perceptible fecal matter had escaped. A rapid search for other openings was made. As no other rupture existed, the injured intestine was resected and a Murphy button applied. In addition to the regular technic, a continuous suture surrounded the intestine over the site of junction of the two halves of the button. The intestines were brought out upon hot towels and carefully washed with normal salt solution at a temperature of 110° F. The abdominal cavity was also flushed out and then dried. Wicking drains were inserted to every part of the peritoneal cavity and the intestines returned. The wound was sutured in part only.

The patient left the table with a pulse of 160. Oxygen was used. He never rallied, but died three hours after the operation.

The vulnerable force may result in injury to the abdominal wall alone, in injury to intra-abdominal viscera alone, or in injury to both wall and viscera. The amount of injury to the abdominal wall may range from simple ecchymosis to rupture of muscular and larger vascular elements. The visceral injury may range from superficial contusion to total disintegration of the walls of the hollow viscera and rupture of the solid viscera.

The extent of injury depends upon the degree of force exerted and the intra-abdominal and intravisceral pressure present. Injuries received when the stomach, gall bladder, large or small intestine, or urinary bladder are more or less full, hence approaching closely the compactness of the solid viscera, are more likely to result seriously as regards the abdominal contents by reason of the lowering of the elasticity and resistance. The presence of adhesions or disease lessens the mobility in the first instance and decreases the normal resistance in the second. The thickness and tone of the abdominal wall plays an important part. If relaxed, intra-abdominal injury is more likely to result. If rigid and of good tone the likelihood of intra-abdominal injury is lessened. It is conceivable, however, that a great force might act in a variety of ways, whatever the resistance of the abdominal wall. The greater omentum, by its thickness and extent, becomes a factor in the distribution of the applied force. The amount of resistance offered by both these structures is more or less a matter of conjecture. Experiments upon the cadaver, as conducted up to the present time, are valueless, as they have been conducted after rigor mortis has been established. Eichel performed numerous experiments upon animals with the details of which I am not familiar. The conclusion at which he arrived was that the severity of the injury depended less upon the amount of force than upon its direction, and upon the tension and thickness of the abdominal wall. It is natural to suppose that the vertebral column will offer more resistance to a direct than to a glancing blow, hence any interposed viscera must suffer accordingly. The site of impact is also to be considered. It would seem, however, that the pressure conditions of the viscera at the time of injury played a more important part in the production of severe injury than either the amount of applied force, its direction, or the resistance offered by the abdominal wall. Commonly the force is exerted through a kick or the passage of a wagon wheel over the abdomen.

Symptoms may be divided into those referable to the abdominal wall or to the abdominal cavity, or both. Also into immediate symptoms and those which may be termed "secondary"—i.e., referable to particular viscera. Symptoms may be continuous throughout, and either mild or severe in character, or they may be slight at first, and later suddenly become alarming.

The first symptoms present are pain, vomiting, and slight distention, coming on in the order named. Pain may be slight or severe. In the cases which have come under the author's observation, pain as an early symptom has not been marked. Vomiting is a constant symptom. Its significance depends altogether upon its persistency. Distention may be slight or wanting at the very onset, and its increase may be slow or rapid. Some observers have noted retraction of the abdominal wall. Rigidity is of value only where it is at first absent and later develops. When present from the onset its cause is probably in the abdominal wall. Shock may or may not be present. When present, it is of value in determining the severity of the injury. In the cases personally observed shock was altogether absent. The term "shock" is not used in this connection in the sense of "collapse," which latter may intervene at any stage. The passage or non-passage of gas or urine for several hours is worthy of note. Temperature and pulse, especially the latter, are of extreme importance. Taking out of account the temperature and pulse of shock, it will be observed that cases of grave intra-abdominal injury have in most cases a steady rise of temperature from the very inicpency of the trouble, and in all cases a continuous acceleration of pulse rate.

Diagnosis.—The first questions relate to the character of the applied force, the site of its external impact, and its direction. Next, the probable condition of the abdominal wall and the viscera; the time elapsed since the last meal; the time when the bladder and sigmoid were last emptied; the history of previous disease of any of the abdominal viscera. The pulse, temperature, and respirations, and the degree of shock, if present, noted. Vomiting, its time of onset, its character, and its persistency. Distention, its time of onset and rapidity, and whether it is extravisceral, as shown by the absence of normal liver dullness. This last is valueless in early diagnosis. By the time the liver dullness is lost the case has usually passed beyond the skill of the surgeon. It is of extreme importance to ascertain

---

* Abstract in Centralblatt für Chirurgie, 1898, xlvi, p. 1115.
whether opium has been administered. Opium, even in small doses, given in the incipiently of intra-abdominal injuries, renders diagnosis difficult, and in many instances impossible. It disguises the true character of the pulse and respiration, lessens the pain and destroys the tenderness, lowers the temperature, frees the rigidity of the rectus, and delays the distention. It should never be administered before diagnosis. The condition of the abdominal wall is noted; also the relation of the rectus to respiration. Having determined that the force was sufficient to produce severe injury, it is not necessary to discover if that injury is located in the abdominal wall, for that is of trifling moment compared to any intra-abdominal lesions; but rather must we apply all aids at our command to ascertain the presence or absence of the latter, its location being of trifling import.

Immediately following severe injury, it is perhaps impossible to arrive at a positive diagnosis. It is needless to remark that all such cases should be closely watched, bearing well in mind the probability of intra-abdominal lesions. The patient or his friends should be warned of this feature in every case. The immediate symptoms may be slight. The pain, vomiting, tenderness, and shock, when present, may be mild in character. If so, and if they are transitory, well and good; the case will probably terminate satisfactorily. But if the initial symptoms persist in ever so mild a form, especially the tenderness and acceleration of pulse, the diagnosis is fairly positive; if, in addition to persisting, they increase ever so slightly, the diagnosis is fairly assured; while if yet further to the increase of these symptoms there is added beginning moderate increasing distention, and a moderate steadily increasing rise of temperature, the diagnosis of grave intra-abdominal injury is made absolute. This is the picture presented by the most insidious cases. In other cases the diagnosis is assured from almost the very start. In practically all cases a few hours' close observation will establish the diagnosis. It is not by the mere presence of the symptoms that a diagnosis is made, but from their persistence and steady increase. Intra-abdominal hemorrhage is present to a greater or less degree in all cases. It may be present in sufficient amount to give rise to symptoms of concealed hemorrhage. The fluid blood may produce dullness over either flank. There is no injury or disease which requires the absolute mastery of physical diagnosis, the exact knowledge of visceral relationship, as is required here. It must be remembered, too, that the fact of a receipt of an injury must be absolutely established. Notwithstanding its difficulties, diagnosis must be made, and made within a few hours of the receipt of the injury, if the patient is to be benefited. The determination of the exact nature of the injury is in many cases impossible in the time afforded, if the life of the patient is to be saved. The nature of the symptoms as outlined above furnish sufficient grounds for an exploratory laparotomy. This should be done in all cases except in those whose condition is so desperate that anesthesia means certain death. Any of the viscera may have received injury and be producing the symptoms, but no time must be wasted in endeavoring to determine which viscus is at fault. If we wait for liver dullness to be obliterated we may not only wait in vain, but will destroy the patient's only chance of recovery. We can not wait for our patient's belly to fill with blood from a ruptured mesenteric or renal vein; we can not wait for the fully developed peritonitis of gall bladder or urinary bladder rupture; we can not wait to establish a definite diagnosis of perforation of some portion of the gastro-intestinal tract, for if we do, we seal our patient's fate.

HODGKIN'S DISEASE.

WITH REPORTS OF CASES.*

By E. G. WOOD, M. D.,

PROFESSOR OF THE PRACTICE OF MEDICINE IN THE UNIVERSITY OF NASHVILLE.

Hodgkin's disease, pseudo-leucæmia, or lymphadenoma, though a comparatively rare disease, occurs with such frequency that few general practitioners fail to see one or more cases of this interesting but somewhat obscure affection, and while the diagnosis in the early stage often presents great difficulties, when well established it presents features so characteristic that the true nature of the case could hardly be overlooked.

The following brief reports of four cases taken from my case book serve to illustrate the principal features of this disease, and two of them are especially interesting as affording some evidence in favor of the specific infectious theory which has been advanced by some observers:

Case I.—J. P., aged thirty-nine years, farmer, consulted me in the summer of 1891 for lumps in his neck, under his arms, and in the groins. Previous to the present illness patient had been a very healthy man, never having consulted a physician before. His family history was very good; father, mother, and ten brothers and sisters living and well, with no history of tubercular, blood, or gland disease. About five months before coming under my observation he had noticed lumps in the right side of his neck, at first small like marbles, but growing rapidly until some of them had attained to the size of a large orange. At comparatively short intervals smaller lumps appeared in the left side of the neck, in both axille, and in both groins, those in the axille rapidly increasing in size to form large masses. About four months after his attention was first drawn to his condition he found that his abdomen had become larger, particularly on the left side, and this growth rapidly increased. He had lost color and strength so that he was now unable to attend to his duties. His weight was reduced by twenty-five pounds. At first he had noticed no fever or disturbance in his general

* Read before the Middle Tennessee Medical Association, May 18, 1899.
a

health, but for about six weeks past had had frequent chills, followed by fever, loss of appetite, moderate diarrhea, and rapid loss of strength, with dyspnea upon exertion and edema in the ankles.

On examination, patient is a strongly built man, but his muscles are soft and flabby, and he shows evid- ence of emaciation. Anemia is marked, and there is shortness of breath on exertion. Numerous enlarged glands are seen on both sides of his neck varying in size from a bean to a large apple, the largest being situated on the right side.

In the axillary and inguinal regions the glands are enlarged, one in the left axilla approaching the size of a large cocoanut. These glandular masses are soft, elastic, freely movable, not matted together, and only slightly tender, the superficial skin looking normal.

The spleen is greatly enlarged, and extends downward to within an inch of the anterior superior spine of the ilium, and forward to within two inches of the median line. It is smooth, regular in outline, but is tender on pressure. Liver measures four inches and a half vertically in the nipple line, and is easily palpable below the ribs. Heart and lungs show no evidence of disease. Temperature taken in the afternoon was 102.6° and pulse 112. Urine normal.

Blood count shows 2,909,000 red corpuscles to the cubic millimetre and 8,600 white cells.

The case progressed rapidly to a fatal termination, chills and fever recurred at almost daily intervals, the glands and spleen rapidly increased in size, anemia became more pronounced, and the patient died from profound asthma eight months from the time when the symptoms were first observed. Before death the large glandular masses in the left axilla ulcerated through the skin, leaving a foul ragged sore. For some weeks before the enlarged glands were first noticed patient had suffered from a troublesome alveolar abscess in connection with the right lower molar tooth.

Case II.—Seen in 1894. A young girl, fourteen years of age, first had enlarged glands in the right, later in the left axilla, and within four months had developed in both sides of neck and both groins. The spleen was enlarged sufficiently to render it distinctly palpable, anemia was a prominent feature, while emaciation was moderate. For a time under full doses of arsenic the color improved and the glands appeared to diminish in size, but after a short period the disease again progressed steadily, the patient dying twenty months after the symptoms were first observed.

Blood examination showed nothing but moderate diminution in red cells.

Case III.—Date of note January 17, 1899. W. M., aged six years, a white boy, native of Tennessee, was quite healthy up to nearly two years ago. His father, mother, and sister are alive and well. His father's father, brother, and two sisters died of pulmonary tuberculosis. There is no history of syphilis or of blood or gland diseases.

Nearly two years ago the boy had a severe attack of non-suppurating amygdalitis, limited to the left tonsil, which was followed immediately by enlarged glands behind the angle of the jaw. These glands slowly increased in size, others beneath the sterno-mastoid soon became affected, and about ten months later those in the left axilla became involved. Six months later the glands in the right side of the neck, right axilla, and later still those in the groin, began to enlarge. Within the past two months a tumor was noticed in the left side of the abdomen, and during this latter period this tumor and the various glands have grown rapidly. For several months he has had irregular febrile attacks, with a temperature ranging from 100° to 102° F., and lasting three or four days to a week, then declining for about two weeks. Has grown anemic and weak, but has lost little flesh. Has had two slight attacks of epistaxis. There has been no pain complained of throughout the case.

The boy is fairly well nourished, but decidedly anemic. Numerous enlarged glands, varying in size from a small marble to a Tangerine orange, are seen on both sides of the neck, chiefly under and in the vicinity of the sterno-mastoid. They are moderately soft, elastic, freely movable, not being adherent to the skin or to one another and not painful on pressure. Skin over glands normal, and presents no old or recent scars. Similar smaller growths are present in both axillae and both groins. The spleen is enlarged to form a large tumor, which extends downward to an inch below the anterior superior spine of the ilium and forward to within an inch and a half of the median line. It is firm, smooth, regular, and movable on inspiration. Liver is enlarged, being four inches in vertical line and felt an inch and a half below the costal margin. It is also smooth and regular in outline. No signs of disease in lungs. Urine normal. Blood shows 2,238,000 red cells, moderate polycythemia. No increase in leucocytes.

May 13th.—About three weeks after date of last note the boy began to improve. This improvement became very marked. The glands grew smaller than they had been since early in the disease. His waist measure decreased two inches, and general health improved. This continued for about a month. Since then he has had febrile attacks, lasting five or six days, with intervals of about two weeks, during which there was a slight increase in temperature. He is now passing through his severest attack. The glands in the cervical regions are enormously enlarged, and his waist measure is now twenty-seven inches. His feet and legs are swelling considerably, and a large hydrocele is developing. A coughy cough, with difficulty in breathing, has also appeared, and his general condition is worse than at any previous time.

Case IV.—Date of note April 24, 1899. Mrs. X., aged thirty years, white, mother of four children, all healthy. Family history very good; no history of tuberculous, blood, or gland diseases, but patient and her brother in early youth suffered frequently with severe attacks of epistaxis. Up to September last patient was a strong and healthy woman of good color, weighing in August a hundred and fifty pounds.

Some time in September last she noticed a small lump in the left side of the neck above the outer third of the clavicle, but as it was small, painless, and caused her no trouble, she paid little attention to it, though similar lumps soon appeared on the right side of the neck. About the end of December she had an attack of "gripee," with fever, cough, and prostration. This reduced her strength to such an extent that in January she was sent to Florida for the balance of the winter. She returned home about the middle of April in much the same condition as when she went away. She gained nothing in strength, had distinctly lost in color, and her weight had been reduced a little more, weighing now only a hundred and nineteen pounds. Cough and dyspnea on exertion persisted, and the lumps were now
present on both sides of the neck, and also in the axillary and inguinal regions. Patient now complains of great weakness, dyspnea on exertion, pulling of the ankles, cough, which is loud, harsh, almost brassy in character, and attacks of suffocative dyspnea at night, especially if she lies on her back or left side. She has no chills, but thinks she is feverish in the afternoons. Her appetite is fair, digestion good, bowels a little loose. No hemorrhages.

On examination, patient is very anemic. Enlarged glands are found in both sides of neck, in axilla, and in groins, ranging in size from that of a marble in the groin to an orange in the neck. They are freely movable, moderately soft, but a little tender on pressure; otherwise painless. Distended veins are seen on the left side of the neck. Spleen is enlarged sufficiently to render it distinctly palpable. Liver normal in size.

From the heart there is continuous dullness up the sternum to the episternal notch; this extends to the right border of the sternum, and to the left to a point two inches from its left border at the upper end, tapering down to the sternal border in the fourth space. Breathing is deficient over the left lung throughout; otherwise no signs of disease in lungs.

Heart gives no evidence of disease. Temperature, 10 A. M., 99.2°; pulse, 108. Temperature, 3 P. M., 100.6° F.; pulse, 112. Urine normal. Blood shows 3,200,000 red corpuscles, 7,800 white.

May 16th.—Since above note patient has less cough, can sleep on either side, the temperature has been normal for nearly two weeks, and she is feeling stronger. No special change can be detected on physical examination except that the left leg has begun to swell throughout its whole length, especially toward night. This is unattended by pain in the leg, but there is pain in the left inguinal region. Reduction in the size of the glands in the neck is noted, and the tenderness has disappeared.

In connection with the reports of these cases it may not be out of place to make a few remarks on the nature of this affection, the origin of which is not yet understood.

Hodgkin's disease—so called after Hodgkin, of Guy's Hospital, who first described it—is characterized by a progressive proliferation of the lymph glands with frequently secondary lymphoid growths in the spleen and liver, and progressive anemia. The superficial glands in the cervical, axillary, and inguinal regions are usually first affected, and later on the mediastinal, bronchial, and retroperitoneal glands.

At first soft and movable, they frequently in the later stages become firm and matted together into large masses, up to the size of an orange or even a large coconut. As a rule they present a uniform grayish-white color on section, and do not caseate or ulcerate through the skin; but occasionally during rapid growth they will burst their capsule, and pressure upon the skin leads to necrosis and ulceration. In about four fifths of the cases the spleen is enlarged from the growth of lymphoid tissue, but it rarely attains to the size seen in leucemia.

The etiology of the disease is still shrouded in doubt. It occurs most frequently in males and in early life. In many cases the patients will give a history of perfect health prior to the onset of the disease, as in Cases II and IV reported.

Irritative lesions in the vicinity of the mouth have preceded the disease in so many instances that some observers have advanced the theory that it is due to infection. Trousseau noted the frequency of this association, and recently Flexner has found in two cases certain protoplasmic foreign bodies which he thinks may possibly be the cause of the disease. Cases I and III support this view. The fact that the disease promptly followed a unilateral amygdalitis in the boy's case almost forces one to the belief that there must have been some relation between the local inflammation and the subsequent disease in the glands, the specific infective agent gaining an entrance through the tonsil.

Symptoms.—The onset of the disease is usually insidious, the patient's attention being first drawn to his condition by the glandular enlargement. Anemia, which is present to a variable degree in practically all cases, usually is first noticed after the affection is well under way and is progressive. Though generally well marked, it is rarely excessive, the blood count usually showing from 2,500,000 to 4,000,000 red cells to the cubic millimetre. The dizzy headaches, faintness, shortness of breath on exertion, noises in the ears, epistaxis, muscular weakness, and oedema of the feet are associated with the anaemia. Fever is present at some period in nearly all cases. It is usually slight and fairly constant, but in some cases occurs at regularly recurring intervals, rising to 102° or 103° for some days, then falling to normal for a week or more, as is shown in Case III. My own observation goes to show that the fever is most marked in those cases which run a rapid course. Osler records a case in which bronzing of the skin was a marked feature.

The glandular tumors usually first appear on one side of the neck, and after a varying period of usually months, but sometimes a few years, they are seen on the opposite side of the neck and in the axillary and inguinal regions. The growths are at first painless, moderately soft, and freely movable, but later in the case they may become firm, matted together, and in some cases produce ulceration of the overlying skin. Their size varies from small nodules to large masses which may press the head over to the opposite side. A peculiar feature is the variability in the size of the glandular masses, which is frequently observed during the course of the disease, as in Case III. The temporary reduction in their volume may be so marked and so rapid as to hold out delusive hopes of recovery to the patient.

In most cases various additional symptoms are seen due to the pressure of the growths on adjacent parts, as, for example, venous distention and oedema from occlusion of veins seen sometimes in the arm or leg, as in Cases III and IV, or pain from pressure on nerves.

The growths in the bronchial and mediastinal re-
regions, by diminishing the calibre of the trachea, may give rise to dyspnea, cough (which is usually harsh and ringing), or partial or complete interference with the admission of air into one lung. These symptoms are well illustrated in Case IV, which also shows the dullness in the upper sternal region caused by enlarged mediastinal and bronchial glands. Pressure on the recurrent laryngeal nerve may cause aphonia.

The spleen is often enlarged, sometimes to a considerable size, as in Cases I and III, but usually the increase in size is only moderate. The blood shows no special changes beyond a moderate reduction in the number of red cells. Unlike what occurs in leucæmia, the leucocytes are not increased.

**Diagnosis.**—In the early stages it is often extremely difficult, if not impossible, to distinguish the disease from tubercular adenitis. The presence of tuberculosis elsewhere may render valuable assistance, but it is well to remember that the two diseases may exist together. In tubercular adenitis the glands in the anterior triangle of the neck are usually affected, while Hodgkin's disease generally first attacks those beneath the sterno-mastoid and in the posterior cervical region. In the former disease tenderness on pressure, signs of inflammation, and a tendency to suppurate are common features, while they are rare in Hodgkin's disease. Enlargement of the spleen is decidedly in favor of the latter. Syphilis may be excluded by the history and the absence of other manifestations of syphilitic disease.

The blood examination will readily serve to distinguish it from leucæmia.

**Prognosis.**—Recovery is very rare, if it ever occurs. I have never seen a case recover. The disease usually runs its course in from one to three years, but it is very variable, some cases lasting several years in a quiescent state, while, on the other hand, Shattuck and Cabot report a case in which the whole course of the disease occupied only seven weeks.

**Treatment.**—From the foregoing remarks it will be readily seen that but little reliance can be placed on therapeutic measures. Arsenic given as Fowler's solution, at first in small doses and gradually increased up to the limit of toleration, certainly has some effect in many cases, improving the patient's general condition and frequently inducing a temporary reduction in the size of the growths, as in Cases II and IV. Phosphorus has been recommended. As there is marked debility, general hygienic measures should be carried out and general tonics administered to support the patient and increase his resisting powers to the disease. Surgical measures are probably of no avail beyond the removal of the deformities.

The Quarterly Medical Journal of London.—It is announced that hereafter the journal will be issued in November, February, May, and August, instead of October, January, April, and July.

**OPHTHALMIC CLINICAL CONTRIBUTIONS.**

**By DAVID WEBSTER, M.D.**

**Case I. Abscess of the Frontal Sinus.**—O. M. B., aged seventy-seven years, a retired broker, came under my observation March 31, 1888. He had been troubled with a "bad catarh" for many years. In October, 1887, a swelling appeared above his left eye. The eye was entirely closed by this swelling at first, but after a time the inflammation subsided to a certain extent, and only a small lump remained, which "lump" was situated just beneath the internal angular process of the frontal bone. Upon palpation this swelling above the inner canthus was found to be soft and fluctuating, and evidently contained a fluid. From the history, and from the objective examination, I came to the conclusion that it was an abscess of the frontal sinus, communicating with the orbit through a fistulous opening in the bone. To confirm the diagnosis I introduced the needle of a hypodermic syringe through the fistula into the frontal sinus and withdrew it filled with a greenish-white fluid which was offensive in its odor. As the patient was without means I sent him to the Manhattan Eye and Ear Hospital for operation and for further treatment. He was admitted to the hospital on April 4th, and having put him under ether, I made an incision about three quarters of an inch in length parallel with the fibres of the orbicularis and through the front wall of the abscess, and evacuated a considerable quantity of thin and very offensive pus. A curet was introduced into the frontal sinus, the granular mass found there was curetted away as thoroughly as possible, and a drainage tube was inserted.

April 10th.—The discharge has not been copious. The wound has been washed twice daily, and the cavity has been syringed out with solution of bichloride of mercury, 1 to 2,500. To-day I left out the drainage tube.

17th.—The external wound being healed, the patient was discharged.

27th.—Pus had collected again, but had reopened the wound and discharged spontaneously. I enlarged the opening and reinserted the drainage tube.

May 5th.—The discharge being very slight, the drainage tube was left out, and the wound was kept open with strips of lint or gauze.

This patient continued under observation for several months longer. The wound was syringed daily some of the time, and at varying intervals the rest of the time. Finally, when not a drop of pus showed itself for a week or two, the external wound was allowed to heal again, and the patient had no further trouble with his eye. Possibly the disease of the frontal sinus would have been cured much sooner if communication had been established between the sinus and the nose at the time of the operation, and had been kept open by drainage tubes and syringing; but the patient was a very feeble, broken-down old man, and I thought it better to use as little violence as possible in his case, even though it should take longer to effect a cure.

**Case II. Unilocular Trachoma with Pannus and Ulcerative Keratitis.**—Kitty H. came to the clinic at the Manhattan Eye and Ear Hospital in December, 1887, with trachoma, pannus, and ulcers of the cornea, left eye. She came several times a week, and was treated with atropine and with glycerole of tannin, and with other local applications, until May 1, 1888, when she was admitted to a bed in the trachoma ward.
May 9th.—As it was thought that the pressure of the upper lid upon the eyeball was tending to keep up the corneal inflammation, ether was given and a cantholysis was done. Iced cloths and atropine constituted the after-treatment. The stitches were removed two days later. The first record of vision was on May 16th, when R. V. = 2/3 and L. V. = counting fingers at two feet.

17th.—Pressure forceps has been used in the mornings, and glycerole of tannin at night.

22nd.—The eye is much improved; the ulcer is healing, and the vascularity of the cornea is disappearing.

June 9th.—The vision of the affected eye is up to 4/6.

11th.—The keratitis is cured. No blood-vessels are visible upon the cornea. The corneal ulcers are healed and only diffuse opacities remain.

July 10th.—The conjunctiva of the upper lid is swollen, and appears as though bordering on acute trachoma. The treatment was changed to iced cloths and sulphate of copper.

20th.—The acute swelling having subsided, the iced cloths and sulphate of copper were stopped and the patient put upon the use of Agnew’s spray.

August 2d.—Left vision = 2/6.

20th.—Left vision = 2/6.

September 1st.—Left vision = 3/6. The inflammatory symptoms having almost entirely disappeared, and the patient being comparatively comfortable, she was discharged from the hospital and directed to attend the afternoon clinics.

Case IV. Marginal Keratitis, Both Eyes, with Ulcer of Left Cornea. September 10, 1888.—Katie R., aged twenty-three years, has had recurring attacks of keratitis for years, and has been treated at various eye clinics. The present attack dates from the 24th of August, since which time she has been treated at the outdoor department of the Manhattan Eye and Ear Hospital. She has marginal keratitis of both eyes and a small corneal ulcer of the left. The eyelids are red and the conjunctive hyperemic. The patient was admitted to a bed in the wards, and put upon instillations of atropine solution thrice daily and frequent bathtings with hot water.

13th.—The right is already quiet and white; the left is looking much better. On admission the vision was = 3/3. The eyes being now thoroughly under atropine, the vision and refraction were tested, and the following results were found: R. V. = 2/6, made 3/6 with + 5.50 D.: L. V. = 2/6, made 3/6 with + 5.50 D. The impaired vision of the left eye is accounted for by slight opacities of the cornea. The results of old corneal ulcers.

16th.—Both eyes being well, glasses + 4 D. were ordered for both eyes and the patient was discharged, with instructions to wear the glasses all the time.

Case V. Syphilitic Iritis with Total Synechia Posterior and False Cataract; Iridecotomy; Vision Unimproved.—Miss Lavenia W., aged thirty-two years, first consulted me at my office on October 6, 1886. The diagnosis was “old iritis with synechia posterior, left eye.” She had R. V. = 3/6; L. V. = to; no improvement with glasses. The eye had been inflamed from February until June, and had been treated only with domestic remedies. There was a history of rheumatism, or pain in the joints, when she was first attacked with the eye trouble. Her left wrist had been swollen and painful. She said that she had had no sore throat, but that her hair had been falling out a good deal, and had not ceased to do so. In September she had been covered, in places, with an eruption like “the hives.” The patient was put upon atropine locally, and mercury with iodide of potassium internally.

November 20th.—The patient made her second visit this morning. The vision of the affected eye is down to counting fingers at two feet. She complains of “floating strings and specks” before the eye. The exudation into the pupil prevents an examination of the fundus. She now has enlarged post-cervical glands, and complains of pain in the back of her head. Her throat has been sore for the last two weeks. Inspection shows syphilitic ulceration of the fauces. She was put upon increasing doses of iodide of potassium.

March 21, 1898.—L. V. = 2.75. She is taking forty-five drops of a saturated solution of iodide of potassium three times a day. She was instructed to continue to increase the dose. This was the last time she came to the office.

May 12th.—She was admitted to a bed in the Manhattan Eye and Ear Hospital. There were then diffuse corneal opacities in addition to her old iritis and false cataract, but she could still count fingers at one foot. The general symptoms of syphilis were in abeyance. The upper part of the cornea was less opaque than the rest of it, and it was thought that an iridectomy upward would not only improve the vision but would put the eye in a healthier condition by facilitating the circulation of the fluids within it. Accordingly, an iridectomy upward was performed, under cocaine anesthesia, and with antisepitic precautions.

15th.—The eye is doing well. There has been no pain and very little reaction from the operation. Ordered atropine to be dropped into the eye night and morning, and the patient to wear medium-smoke equilites.

18th.—The patient was discharged with the eye looking very well and feeling very comfortable, but with the same vision as before the operation. The right eye was at no time involved.

327 Madison Avenue.

A CASE OF

ACUTE ALCOHOL POISONING IN A CHILD.

By MAURICE A. WALKER, M.D.,

MELROSE, MONT.

Cases of acute poisoning by alcohol in children, followed by death, being not very frequent, I report briefly the following:

Willie L, six years and three months old, of good family and personal history, unaccustomed to the use of alcohols, bright and well developed for his age. At some time between 8.30 and 9.30 A.M., before they had eaten breakfast, he went with his two brothers, aged eight and four years, to a closet where whisky was kept. Each poured out and drank undiluted whisky from a glass capable of holding about three ounces and three quarters. From the description given by the oldest boy, Willie probably drank about three ounces, and each of the other children about two ounces. The parents knew nothing of the escapade until about 9.30, when, on sitting down to breakfast, Willie first dropped a plate and then fell from his chair. At
The Treatment of Intertrigo.—The Riforma medica for June 22d gives the following as Besnier's formula:

R Quinine olate 1 part;

Salol .................. 8 parts;  

Menthol .................. 5 

Ether .................. 8  

Lauryl .......................... 60  

M.

A Specific for Menstrual Disturbances.—According to the Journal of the American Medical Association for August 12th, Professor Hirth, of Munich, was for two years superintendent of the European customhouse at Chung King, the metropolis of western China, Mongolia, and Thibet, where his attention was called to the tang kui root, which has been used for many centuries in China as a remedy for menstrual disturbances. He and others have been testing it, and he is strongly inclined to believe that it is the long-sought specific for amenorrhea without abortifacient properties. He describes it and its action in the Münchener medizinische Wochenschrift, No. 23.

Ipecac in Atonic Dyspepsia.—Lyon médical for July 2d cites two formulœ of Dr. Mathieu's as follows:

1. R Tincture of physostigma ..... 6 parts;  

Tincture of ipecac 1 part;  

Tincture of star-anise 5 parts.

M. S.: Six drops, in a glass of Vickery, after each meal.

2. R Tincture of ipecac,  

Tincture of calumba, equality parts.  

Tincture of gentian.

M. S.: From fifteen to thirty drops after each meal, in two portions from half an hour to an hour apart, in a little water.

For Herpetic Affections of the Cornea.—M. Galezowski (Recueil d'ophthalmologie; Journal des praticiens, July 22d) recommends the following pomade:

R Vaseline 150 grains;  

Neutral hydrochloride of cocaine ¾ grain;  

Porphyryzed iodoform 1 ½ grains.

M. Hot applications and sprays of weak carbonized water, once or twice daily, may be used in addition.

Oxycamphor as a Remedy for Dyspnea.—Jacobson (Berliner klinische Wochenschrift, 1899, No. 16; Wiener medizinische Blätter, 1899, No. 30) recommends the use of "oxaphor" (a fifty-per-cent. alcoholic solution of oxycamphor) according to the following prescription:

R Oxaphor 10 parts;  

Alcohol 20  

Tincture of licorice 10  

Distilled water, enough to make 150  

M. S.: A tablespoonful three times a day.

He has usually found the drug of service in dyspnea, whether of pulmonary, cardiac, or renal origin.

Therapeutical Notes.

For Dental Caries.—The Riforma medica for June 17th ascribes the following to Dauchez. Introduce into the dental cavity, previously dried, a plug of cotton impregnated with one of the following preparations:

R Hydrochloride of cocaine,  

\{ each, 1/4 grain;  

Menthol,  

Liquefied crystals of carbolic acid 1 drop;  

Essence of cloves 75 grains;  

Camphorated alcohol 120 "  

M.

Or—

R Orthoform,  

Carbolic acid,  

\{ each .... 15 grains;  

Camphor,  

Chloral hydrate,  

\{ each .... 60 "  

M.

Ipecac Enemata for Habitual Constipation.—Dr. R. Blondel (cited in the Gazette hebdomadaire de médecine et de chirurgie for May 25th) recommends the use of this formula:

R Aqueous extract of ipecac 1 part;  

Distilled water 5 parts.

M. From a half to a full coffee-coopful, in about five ounces of water, to be used in the morning as an enema and retained until it is absorbed, usually about half an hour. Generally a normal movement will occur in the evening, and in some cases there will be one every day for two or three days. There is no pain or nausea produced by the remedy.

August 19, 1899.
ANÆSTHETICS AS A CAUSE OF PARALYSIS.

He who upsets an erroneous doctrine sometimes performs as important a service as he who establishes a new one. Such a service seems to have been performed by Mally, who has made a study of thirty-six cases of paralysis such as authors have been inclined to impute to anaesthesia (Revue de chirurgie, July). In ten of them, he finds, there was a central lesion that accounted for the paralysis; six of them were hysterical; seventeen others he classes as peripheral, and proceeds to investigate them seriænum; and the three remaining cases he sets down as reflex. It is noteworthy that, of the seventeen peripheral cases, eight were observed by the author personally, and perhaps it was that fact that led him to make the investigation.

Mally rejects the idea that there is any connection at all between anaesthesia and the hysterical and reflex paralyses. Those of central origin may be due indirectly to the anaesthetic, which in a purely mechanical way leads to the rupture of a blood-vessel in the brain. The peripheral paralyses, which are rather frequent, are always, he finds, due to compression, and the anaesthesia has only this to do with them, that it favors involuntary or accidental compression of nerve trunks or the roots of the brachial plexus in the course of an operation. There is no evidence, he says, to show that the toxic or depressing action of the anaesthetic has anything to do with giving rise to paralysis, and any such action on the nervous system is only hypothetical.

As regards the treatment of these paralyses, it is both preventive and curative. During anaesthesia the patient’s arms should not be forcibly drawn up, and care must be taken that none of the limbs are allowed to hang over the edge of the operating table or suffer compression by the weight of the patient’s body or by any ill-placed constricting band. As to the curative treatment, cases of central or hysterical origin present no different indications from those afforded by such paralyses in general. The peripheral paralyses due to compression may be treated with advantage by the ordinary procedures of localized faradization, and they should be applied as soon as possible. When the reaction of degeneration is present, however, localized electrization must be avoided. The wasting of muscles about the shoulder joint that is apt to result from paralytic immobilization may be prevented by resorting early to passive motion of the joint. The grave reflex paralyses should not be treated by localized electrization, but the reflex irritability of the spinal cord may be moderated by sedative applications of static electricity, by the "electric wind,” and, if it is indicated, by revulsion over the vertebral column by means of friction and sparks.

STRETCHERS AND BLANKETS IN RAILWAY SURGICAL SERVICE.

In Macon, on April 18th, there was held the ninth annual meeting of the Central of Georgia Railway Surgeons’ Association. Apparently the meeting was not confined to members of that particular association. One of the company’s surgeons, Dr. George C. Trimble, of East Point, Georgia, read a paper entitled The Need of Stretchers and Blankets in Railroad Service, which is published in the Railway Surgeon for June 27th. Dr. Trimble’s paper was brief, and he introduced his subject modestly, remarking that it might have been under consideration before. He then proceeded to draw a forcible picture of the suffering that might be saved, in many cases of railway injury, if the surgeon had at his disposal suitable stretchers on which the wounded might be conveyed comfortably to a place of refuge and a supply of blankets to aid in preserving the natural warmth of the body when the patient was suffering from the shock incident to a severe injury.

Dr. Trimble’s paper evoked a satisfactory discussion of the matter of stretchers, and it is gratifying to learn from the published account of that discussion that the larger railways of the country are adequately provided with those useful accessories to the care of persons injured in railway accidents. On the whole, the army stretcher was considered satisfactory. The matter of blankets, however, does not seem to have been discussed to any adequate extent. It came out that in case of accident the railway companies were not infrequently obliged to attempt to borrow blankets from families living in the vicinity of the site of an accident, and that they often encountered a decided unwillingness on the part of families, even those of negroes, to contribute from their bed-clothing in cases of need. This does not speak well for the humanity of the people among whom the speakers’ efforts had been made, but it does speak loudly in favor of provision being made by the companies for sufficient supplies of blankets to make the victims of accidents as comfortable as warmth can make.

DEUTSCHE KLINISCHE WOCHENSCHRIFT.

[Text continues...]

PHRENOLOGY EXTRAORDINARY.

For the most part, the "phrenologists" have heretofore been content to exploit the cranium, but the "orificial surgeons" can "give points" to the disciples of Gall and Spurzheim. In the current number of the Atlanta Journal-Record of Medicine there is a delicious editorial on an excerpt from the Journal of Orificial Surgery, an entire octavo page of character interpretation based on the inspection of a young school-teacher's vulva, vagina, and rectum, in which latter there were "fine pockets." "All this," says the Journal-Record, "because of a pouting vulva and a spiny hymen, a condition which, to the uninitiated, would suggest masturbation, but to the observation of the orificial surgeon indicates extreme force of character. If a sensitive hymen indicates superior mentality, by the same reasoning a urethral caruncle suggests genius too lofty for the finite mind to grasp. 'We have before us material for volumes of thought, out of which should come light to every physician that reads.' Not only that, but what is more to the point, the surgeon, while swabbing out the vagina, might be able to glean from a study of the vulva some notion of the patient's ability to pay." We may suggest that, in the case commented on, the "geniologist," while professing to instruct a class, was in reality endeavoring to impress his patient.

THE TEMPERATURE OF THE AGED.

It seems to have been the general impression that the temperature of the blood became a little higher in advanced age than in the previous years of life, but Chelmonski (Deutsches Archiv für klinische Medizin, lix, 1, 2; Deutsche Medicin-Zeitung, July 24th) combats this view on the strength of thorough observations of over a hundred persons. Indeed, he finds that the temperature gradually tends to fall a little below what is considered the normal point. Moreover, the type of its diurnal cycle is reversed; it is higher in the morning than in the evening. There is something besides the figurative, then, in "the hot blood of youth."

THE INFLUENCE OF ODORS UPON THE MILK OF COWS.

The Écho médical du Nord for July 16th contains an interesting note on this subject. After referring to the well-known powers of milk for absorbing odors which flavor the milk—e.g., those of onion, turpentine, tobacco smoke, etc.—if the milk is allowed to stand in...
an atmosphere impregnated with them, the Echo cites a paper by Dr. Virt from the English Journal of the Royal Society of Agriculture, in which instances are adduced where a number of milch cows, having to pass a decomposing calf's body on their road to be milked, apparently imbibed the odor to such an extent as to distinctly taint their milk, and not only theirs, but that of other cows with which they mingled prior to milking. In another case the milk of twenty-five cows was tainted with a horrible odor. On searching for the cause, these cows were found to be pastured near the decomposing body of a horse. In both cases the removal of the carcass sufficed to put an end to the trouble. These observations show not merely the danger of leaving drawn milk in unwholesome places, but the absolute necessity for perfect cleanliness and sanitary environment for milk herds. Further, they suggest the idea that odors may materially influence the vital processes of the body and its secretions, and not merely prove disagreeable sensations and nerve disturbers, and they lend color, moreover, to the material doctrine of the olfactory sense.

**ANOTHER SECRET CURE FOR THE DRINK HABIT.**

From the *British Medical Journal* for July 29th we learn that a new cure for the drink habit, called the "Hayden Treatment," has recently been launched in Liverpool. It purports to be effected by the use of a certain drug discovered by an Irish-Canadian of the name of Hayden. The institution in which this treatment is carried out has the support of very many eminent names among the laity, and is conducted on original lines, the patients being allowed to enter under assumed names, and not being subjected to any restraint. The table is said to be good, recreations are amply provided for, and alcoholic liquors are supplied to those who do not wish to entirely dispense with them. The cure is said to be accomplished in three weeks, and to be permanent in seventy-five per cent. of the cases; though how this latter deduction can be arrived at, considering the receipt period of the introduction of the treatment, is not stated. But worst of all is the necessity, which is emphatically insisted on, of keeping the nature of the drug employed a profound secret. We can only agree with the writer in the *British Medical Journal* that "so long as the nature of the drugs used is kept a secret, the medical profession will look upon the scheme with great suspicion," in this country as well as in England.

**POST-CONCEPTIONAL SYPHILIS.**

M. Fabre and M. Patel (Lyon médical, July 16th) recently presented to the Lyons Society of Medical Sciences photographs of placental sections made in the laboratory of Professor Pochier, from cases of post-conceptional syphilis, contracted in the third, fourth, and seventh months of pregnancy. On the fetal side of the placenta, periarteritis and endophlebitis were constantly present. In the interior of the villi the cells were less numerous and their nuclei less colored than normally. The external epithelium of the villi was especially affected, being either destroyed or proliferated. On the maternal side the decidua was hypertrophied. Its line of junction with the intervillous tissues, in place of being regularly festooned, formed cones penetrating into the interior of the chorion. The cells of the decidua were rarely normal; they preserved all their proper dimensions, but were separated by a layer of fibrin, or agglutinated together. The membranes themselves were altered; there was a true amnionitis, the cells being irregularly nucleated and stratified, and the fibres of the chorion were separated. In the face of changes such as these, it would seem impossible that a fetus developed under such conditions could be born free from syphilitic infection.

**DEATH IN CONSEQUENCE OF PROLONGED LAUGHTER.**

Wachholz (Przeglad lekarski, July 1st; Klinische therapeutische Wochenschrift, July 23d) relates the case of a peasant girl, eighteen years old, who was seized in a field by two fellows and tickled violently on the breast. She died as a result of laughter produced by the tickling. The author explains the occurrence of death from laughing as follows: Laughter consists of an inspiration followed by short and more or less deep expirations. In forcible expiration the abdominal muscles contract and compress the intestines and the diaphragm. Long-continued pressure on the diaphragm acts upon the vagus and diaphragmatic nerves, exciting them and finally paralyzing them. We are not convinced that this is an altogether satisfactory explanation. Certainly the mechanism of death from laughing, if it ever occurs in a healthy person, is worthy to be studied by the physiologists.

**GANGRENOUS MASTITIS.**

According to H. Roger and Garnier, who recently reported a case of this sort to the Paris Society of Biology (Gazette hebdomadaire de médecine et de chirurgie, July 20th), gangrenous inflammation of the breast has not before been observed. Their case was in a lying-in woman who was attacked with scarlet fever. A special microcoecus was found in the pus, similar to microcoeci described by the veterinarians as occurring in the mastitis of animals in the course of lactation, but not proved to be identical with any of them.

**SYPHILIS WITHOUT A PRIMARY CHANCRE.**

Treatment for July 27th quotes from the *Lancet* for May 20th the case of a man who contracted gonorrhoea in January and in March had a roseola, but without any chancére, and subsequently secondary syphilides, followed by sore throat and mucous patches on the prepuce. Comment is made by Treatment on the imposibility of a chancére in a man with a freely movable prepuce, as in this case, being missed if carefully looked for, though in women "there is also the possibility of its being hidden away out of sight in some fold of the vagina, and so escaping notice." We should like to know if the patient in this case was carefully explored to ascertain the possible existence of an intra-urethral chancére.

**CHRISTIAN SCIENCE AS A PUBLIC DANGER.**

According to the *New York Times* for August 16th, Mr. John A. Barnes, counsel for the Illinois State board of health, will undertake an investigation into the death of a girl, eleven years of age, who died from diphtheria while under treatment by a Christian Scien-

  - Calcutta, India | June 24-July 1 | 6 cases.
  - Straits Settlements, Penang Jan. 1-June 30 | 42 cases, 33 deaths.

**Loyalty and Lockjaw.**—Under this heading the British Medical Journal for August 5th has the following remarks upon the epidemic of lockjaw following Fourth-of-July celebrations: "Americans are demonstrative in their patriotism, and their feelings of loyalty to their flag are apt to find vent in manifestations of which the leading motive is noise. For the proper celebration of the Fourth of July, which is the anniversary of the Declaration of Independence, able-bodied citizens deem it their duty to make the welkin ring with every instrument of acoustic torture, and to shout themselves hoarse and each other deaf with barbaric yells. The day is made still more hideous by the firing of guns and pistols. The general effect is such as sensitive persons get from Hogarth's Enraged Musician, multiplied by a figure representing the male population of the United States. What may be the general results of these annual saturnalia of noise to the hearing apparatus and nervous equilibrium of the people can only be conjectured. But on one point definite information is forthcoming. The Fourth of July this year was followed by something like an epidemic of tetanus. Of a hundred and forty-four deaths which occurred throughout the States as the direct consequence of the celebration of the Declaration of Independence, eighty-three were due to tetanus. Of these, twenty-six occurred in New York or its immediate neighborhood. In almost every instance the tetanus was the result of a pistol-shot wound of the hand received on the Fourth of July. The toy pistol, it is said, is responsible for these fatalities, the wad of the blank cartridge penetrating deep into the tissues of the hand, which we hope it is no offense against the majesty of the American people to assume was in most cases not ideally clean. A considerable proportion of the cases were treated with antitoxine, in most instances by means of intracerebral injections. The percentage of recoveries is not accurately known, but it is certain that a large proportion of the patients died. Nearly all these victims of national sentiment were young lads. Their country could doubtless have better spared an equal number of Fourth-of-July orators, and poetic justice would have been satisfied if those valuable persons had been overtaken by lockjaw."

**A Bureau for Physicians Visiting Paris.**—According to the University Medical Magazine for August, Dr. Frederic Gerin Lajoie, an American surgeon resident in Paris, has obtained the necessary authority from the directeur de l'enseignement supérieur and the dean of the faculty of medicine to establish an information office at No. 21 rue de l'Ecole de médecine. His idea is to provide visiting American physicians who come to Paris to study the French systems of practising medicine with every detail of information which would facilitate the object of their stay in Paris.

**Change of Address.**—Dr. Charles N. Haskell, from No. 301 Allyn Street, Hartford, to No. 343 State Street, Bridgeport, Connecticut.

**Army Intelligence.**—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 5 to August 12, 1899:

- **Bailey, Guy G.,** Acting Assistant Surgeon, United States Army, is assigned to and will report at the United States General Hospital, Presidio of San
Francisco, for temporary duty, awaiting transportation to Manila.

Bath, Thomas, Acting Assistant Surgeon, United States Army, will report to the commanding officer of the United States troops on the transport Indiana for duty during the voyage of that vessel to the Philippine Islands and return to San Francisco.

Howard, Deane C., Captain and Assistant Surgeon, United States Army, will proceed to West Point, New York, for temporary duty.

Monson, Edward L., Captain and Assistant Surgeon, United States Army, will report to the commanding officer at Washington Barracks, D. C., for temporary duty.

Raymond, Henry L., Major and Brigade Surgeon, United States Volunteers, will report to the commanding general of the First Division, Eighth Army Corps, for duty as chief surgeon of that division.

Stearns, C. H., Acting Assistant Surgeon, United States Army, will report to the commanding officer of the United States troops on the transport Indiana for duty during the voyage of that vessel to the Philippine Islands, and return to San Francisco.

Ware, L. Y., Captain and Assistant Surgeon, United States Army, is directed to report to Shafter, William R., Major General, United States Volunteers, president of the army retiring board at San Francisco, for examination.

Woodruff, Charles E., Captain and Assistant Surgeon, United States Army, is relieved from further duty at Benicia Barracks, California, and will proceed to Fort Riley, Kansas, for duty, to relieve Powell, Junius L., Major and Surgeon, United States Army, who will proceed to San Francisco for temporary duty.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Week ending August 12, 1890:

Arnold, W. F., Passed Assistant Surgeon. Granted extension of sick leave for one month.

Haas, H. H., Assistant Surgeon. Detached from the Oregon and ordered to the Naval Hospital, Yokohama, Japan, for treatment.

Moore, J. M., Passed Assistant Surgeon. Ordered to the Vermont.

Pickrell, G., Passed Assistant Surgeon. Detached from the Baltimore and ordered to the Monterey and to the Cavite Naval Station.

Wright, B. L., Assistant Surgeon. Detached from the Vermont and ordered to duty with the Second Marine Battalion for Manila, and, on arrival, to report to the commander-in-chief of the Asiatic Station, for duty.

Promotions.

Streets, T. H., and Waggner, J. R., to be medical inspectors.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending August 10, 1890:

Brooks, S. D., Surgeon. To proceed to Augusta, Maine, for special temporary duty.

Bunce, Rupert, Passed Assistant Surgeon. To proceed to Columbia, Washington, for special temporary duty.

Frick, L. D., Assistant Surgeon. To report to Passed Assistant Surgeon A. C. Smith for duty.

Tomp, W. C., Acting Assistant Surgeon. Granted leave of absence for seven days.

Richardson, S. W., Hospital Steward. To report at Washington, D. C., for assignment to special temporary duty. To proceed to Norfolk, Virginia, and report to Passed Assistant Surgeon A. C. Smith for temporary duty.

Gibson, Frank L., Hospital Steward. Relieved from duty at the Delaware Breakwater Quarantine Station and directed to report at Washington, D. C., for temporary duty.

Comfort, N. C., Hospital Steward. To proceed to Hampton, Virginia, and report to Surgeon J. H. White for temporary duty.

Promotions.

Magruder, G. M., Passed Assistant Surgeon, commissioned as surgeon.

Kinyoun, J. J., Passed Assistant Surgeon, commissioned as surgeon.

Appointments.

Wahanik, Charles A., of Illinois, to be junior hospital steward.

Births, Marriages, and Deaths.

Married.

Young—Gearing.—In Annapolis, Maryland, on Friday, July 21st, Dr. Henry Dudley Young and Miss Jessie Lee Gearing.

Died.

Johnson.—In Huntsville, Alabama, on Wednesday, August 9th, Dr. James T. Johnson, in the sixty-ninth year of his age.

Kemble.—In Salem, Massachusetts, on Monday, August 7th, Dr. Laurence G. Kemble, aged thirty-seven years.

Kortright.—In Middletown, New York, on Monday, August 14th, Dr. James Little Kortright, of Brooklyn, in the forty-eighth year of his age.

Leighton.—In Brooklyn, on Saturday, August 12th, Dr. Nathan W. Leighton, in the sixty-seventh year of his age.

Obituary.

Colonel Andrew K. Smith, M. D., of the Army.

Dr. Andrew K. Smith, who died suddenly on the 14th of August, at Cranston's Hotel, near West Point, New York, was a surgeon of the United States Army, and was retired in 1890 with the title of colonel and medical inspector. After graduation in medicine he was appointed to the house staff of the Emigrants' Hospital, Ward's Island, New York, and in 1853 entered the army as assistant surgeon. Five years thereafter
he reached the grade of captain and was promoted to
the full surgeonship, with the rank of major, at the
beginning of the civil war, in which he served with
great distinction. For faithful and meritorious service
in that war he was brevetted lieutenant-colonel. Dr.
Smith was a large-hearted man, beloved by his many
friends in and out of the army. His bereaved widow
has the consolation of a loving son who distinguished
himself in the army medical staff during the Cuban war.

Letters to the Editor.

THE MOSQUITO AS A VEHICLE OF MALARIA.

LOUISBURG, N. C., July 31, 1899.

To the Editor of the New York Medical Journal:

Sir: I have read with interest recent articles on
malarial infection appearing in the New York Medical
Journal. I believe this to be a subject of almost universal in-
terest to the profession, certainly not less to us of the
South than to others. It is quite an important one,
when the question of exterminating malaria is consid-
ered.

Noticing the inclination of writers to favor the the-
ory of inoculation by the mosquito as an important
mode of infection of the human being, I have wondered
how such could be the case when conditions here offer
to this method no support as a fact and little as an
hypothesis.

Residing here, I speak knowingly of sections of easter-
n North Carolina (not the extreme east) in which
malaria is a formidable foe to health, all types of the
disease being seen; yet the mosquito is not troublesome,
and rarely does one hear its characteristic buzz. Of
course, mosquitoes exist in certain places favoring their
development.

To cite an instance of one of our largest southern
seaport cities, with which I am familiar: mosquitoes for
several months in the year are a veritable pest, but
malaria is not a pronounced cause of disease; and many
of the inhabitants deny that malarial poisoning may be
contracted there (I suppose by reason of the salt air and
water). At any rate, the prevalence of the mosquito
and that of malaria are by no means proportionate. I
might add that the surrounding country is decidedly
malarious, and mosquitoes are likewise plentiful, but
the inhabitants use surface water for drinking, while
those of the city do not.

This latter fact would seem to favor the theory that
mosquitoes are responsible for malarial infection
through drinking water.

It is not in any sense of argument that I write, but
with the hope that in the contemplation of exterminating
malaria, facts against as well as hypotheses in favor
of inoculation of the malarial organism by the mosquito
may be duly considered. THOMAS W. DAVIS, M. D.

CORRECTIONS TO DR. ROSE’S LETTER ON APPEN-
DICITIS, ETC.

126 East Twenty-ninth Street,
New York, August 7, 1899.

To the Editor of the New York Medical Journal:

Sir: In my letter of reply to Dr. Ellis, in your issue
for August 5th, I notice two errors, which you will
kindly permit me to correct: 1. The commas in Wurm,
Fortsatz, Entzündung should have been omitted. It is
a matter of choice to write Wurm Fortsatz Entzündung
or to combine these three into one word. You may
write Hof Rath or Hofrath. Foreigners are in the
habit of complaining of long German words—that is,
of combinations like the one under consideration—such
combinations are characteristic of German and of Greek,
and are looked upon as special advantages of these
two languages. 2. It should read äöertröps, and not
döertröps.

A. ROSE, M. D.

232 East Seventy-eighth Street,
New York, August 7, 1899.

To the Editor of the New York Medical Journal:

Sir: I wish to call the attention of the readers of
your valuable paper to the fact that the vocative of the
Latin word doctor is doctor, not doctore. The latter
form I find in Dr. A. Rose’s letter in the Journal
August 5th, in the explanation, “Si tacuisses, Doc-
tore!” This grammatical lapsus has to be corrected
for the very reason that it seems to come from an emi-
nent linguistic reformer whose example might be imi-
tated. Should the mistake have happened in your
office, I beg our esteemed colleague’s pardon.

MAX TALMey, M. D.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By ARTHUR N. TAYLOR, LL.B.

XXXII.

CIVIL MALPRACTICE, INCLUDING GENERAL LIABILITY
OF PHYSICIAN TO PATIENT.

(Continued from page 244.)

Right to Perform Autopsy.—Somewhat analogous to
the right of the surgeon to operate upon a patient is the
right of the physician to perform an autopsy; except
that, from the nature of the case, the consent of the
subject cannot be gained in the latter class of
operations.

Upon the legal status of a dead body there is an
almost confusing wealth of legal lore coming down to us
through the English courts from the early days of
Christian England. The burial of the dead in church-
yards in England is supposed to have been introduced
by Cuthbert, Archbishop of Canterbury, in the year
250. Whereupon the protection and control over the
repose of the dead gradually passed from the authority
of the secular courts to that of the ecclesiastical tribu-
nals. The secular courts, being deprived of all author-
ity over the dead, looked upon the cadaver as not being
the subject of a property right, but confined themselves
to the protection of the monument and other external
emblems of grief erected by the living. Lord Coke,
chief-justice of England, expressed this condition in the
learned and ponderous style of his time as follows: “It
is to be observed that in every sepulchre that hath a
monument two things are to be considered—viz.,
the monument, and the sepulture, or burial of the dead.
The burial of the cadaver—that is, caro data vermis-
is nullius in bonis, and belongs to the ecclesiastical
cognizance; but as to the monument, action is given, as hath been said, at the common law for the defacing thereof."

That adequate protection to the dead is necessary is too obvious to permit of discussion; and as the ecclesiastical court is unknown to our government, the functions which in England vested in that court must here be exercised by our courts of law.

In exercising these functions relative to the subject under consideration, they have, perhaps with a single exception, in respect to the learned precedents of the English courts, refused to hold a dead body as strictly property, yet they recognize and protect the right of the relatives of a deceased person to the custody and control of the body.

The relatives in whom this right vests are, first, the husband or wife of the deceased; second, if no husband or wife survives, then the children; third, if there is no husband or wife and no children, then, first, the father, second, the mother; fourth, after them the brothers and sisters of the deceased; fifth, after them the next of kin, according to the course of the common law, to the remotest degree, according to the law of descent of personal property.

This right involves and carries with it a duty; more particularly, it is both a right and a duty: a right to the custody, care, and protection of the body of the deceased from the moment the breath leaves it, and the duty of according to it decent Christian burial.

In referring to this right, in the case of Foley vs. Phelps,† Justice Patterson said: "The right is to the possession of the corpse in the same condition it was in when death supervened. It is the right to what remains when the breath leaves the body, and not merely to such a hacked, hewn, and mutilated corpse as some stranger...may choose to turn over to an afflicted relative." In this case the question arose, for the first time in New York, whether one performing a post-mortem examination without the consent of the widow of deceased was liable to her in damages. The court in a learned and elaborate opinion examined the law and the principles applicable to the case, and came to the logical conclusion that whenever the widow's "right to the possession of the corpse in the same condition it was in when death supervened" was violated, such violation furnished a ground for a civil action for damages.

Practically the same question had arisen in the case of Larson vs. Chase,‡ in which the court not only held there was a cause of action, but that mental suffering caused by the unlawful act was a distinct element of damages.

In the case of Burney vs. Children's Hospital,* a father placed his child in a hospital for treatment; the child died, and a post-mortem examination was performed without his consent. The father brought suit against the hospital for damages. The court, following the reasoning of the former decision, said: "The father, as the natural guardian of the child, was entitled to the possession of its body for burial. Being entitled to the possession of the body for the purposes of burial, is not his right against one who unlawfully interferes with it, and mutilates it, as great as it would be if the body were buried in his lot, and was thence unlawfully removed? That an action may be maintained in the latter case we have already seen, and we are of the opinion that it may be in the former."

As both reason and justice commend the conclusion arrived at by these courts, there can be no doubt that the precedents will be followed whenever the question arises, and that a physician who performs an autopsy without the consent of the person having the right of custody of the deceased, does so at his peril.

There are, however, cases in which such operations may be performed without consent and yet no liability exist; these cases are where the post-mortem is performed in accordance with the directions of law. The statute law of most States provides that whenever a person is found dead, and the cause of his death is not apparent and can not be ascertained from the evidence given or from a superficial examination of the body, the coroner shall order an examination to be made. Such an examination, to be safely made, requires no consent from the relatives of the deceased, for it is sanctioned by positive law. An interesting case of the sort is that of Young vs. College of Physicians and Surgeons of Baltimore City. In this case the deceased, who, in coupling cars, sustained a severe injury to his right leg, it being mashed below the knee and almost severed from the body, was taken to a hospital, where he died next day. The evidence showed that the deceased was a strong, stout man, and of good nerve. A fellow-laborer testified that he had worked with deceased five years, during which he had lost no time. After the death a post-mortem examination was ordered by a Dr. G., a coroner, and performed by a certain Dr. K., both of whom were made defendants to the suit. Evidence was offered on the part of the plaintiff for the purpose of showing that the post-mortem was without the widow's consent; that the body was wantonly cut, mutilated, and disfigured, and the feelings of the relatives of the deceased were inhumanely outraged.

On behalf of the defendants it was shown that Dr. G. was a coroner, and that Dr. K. was medical examiner, appointed by the board of health; also that the post-mortem was ordered by Dr. G. as coroner. Dr. G. testified that he ordered the autopsy because he wished to know the cause of death; that it had been reported to him that the man's leg had been cut off by the train and that he had died within thirty-six hours after he was brought to the hospital, that he did not think the loss of the leg in this way sufficient accounted for the death, and that he could not give the death certificate without having a post-mortem. Dr. K. testified that he did not think in the majority of cases persons in ordinary health, when the leg was crushed below the knee, would die from shock. A certain expert testified that if a healthy man should have his leg crushed off, he would not think it a sufficient cause to explain the death, and in such case, if his official duty required him to give a death certificate, he would make every effort to obtain a post-mortem; and that it was so unusual for a death to occur from accident under the conditions surrounding the deceased that other explanations were more probable. Another expert testified that when a man's leg is cut off below the knee, and he dies within thirty-six hours after the injury, the accident would not be an entirely satisfactory explanation of the death, if the man was ordinarily healthy and muscular; and,

---

* Third Inst. (Coke), 263.
† Foley vs. Phelps, 1 App. Div., 551.
‡ Larson vs. Chase, 47 Minn., 307.
* Burney vs. Children's Hospital, 169 Mass., 57, 38 L. R. A., 413.
* Young vs. College of Physicians and Surgeons of Baltimore City, 81 Md., 558, 32 Atl. Rep., 177.
if he was required to determine definitely the cause of death in such a case, he would not consider that he had done his duty without having an autopsy. Dr. K. described his proceeding in making the autopsy—the taking out of the brain, the opening of the body, the removing and cutting into the different organs, the liver, spleen, kidney, lungs, and heart. He testified that an examination of all the vital organs was necessary to determine the cause of death; that the cause of death was persistent heart shock; that deceased had fatty kidneys and fatty degeneration of the heart; that the injury itself was not of such a nature as to have caused persistent heart shock, unless there was something else besides the injury that helped to produce it. Expert evidence was also given to the effect that a complete examination could not be made without removing and opening the brain.

In the city where the present case arose the law provides that "when any person shall die in the said city it shall be the duty of the physician who attended during his or her last illness, or the coroner, when the case comes under his notice, to furnish within forty-eight hours after death . . . a certificate setting forth as far as the same can be ascertained . . . the cause, date, and place of death." In summing up the conclusion of the court in this case, Justice Roberts said: "The evidence before us exhibits the case of a public officer, whose duty it is to find out and certify the cause of a death which is brought to his notice. The accident preceding his death, and disabling him, is not, in his opinion, sufficient to cause the death of a healthy person. There must, therefore, as he thinks, be some diseased condition of the injured man which contributed to bring about this result. His opinion is shared by other reputable physicians who have testified in the case. He could not honestly and conscientiously give the certificate which the law required him to give unless he made proper inquiry into the case. In his judgment, and in the judgment of the professional witnesses, proper and sufficient inquiry could not be made without an autopsy. So far as the evidence in the case shows, or any rational inference from it, the coroner did simply his plain and positive duty in ordering the autopsy. And the medical examiner, Dr. K., was equally obliged by his duty to obey the order of the coroner."

Under the law quoted above, in compliance with which the coroner directed the post-mortem examination, no reason can be detected why the attending physician might not with equal right and justification have conducted the examination in the coroner's absence. A case involving this particular question arose in Denver not many years ago. There a law was in force similar in effect to the one above quoted, which required the physician to give a certificate of death before a burial permit could be obtained. In this case the deceased was stricken dead while riding in a carriage, and was taken to an undertaker's to be prepared for burial. While there, deceased's regular attending physician was applied to by the undertakers for a death certificate, whereupon he performed a post-mortem. Suit was commenced against the undertakers and the physician, but the court held that they were not liable. Justice Richmond, in his opinion, said: "I think that the evidence discloses circumstances which would warrant any physician in declining to issue a certificate designating the cause of death, and permitting burial, without a post-mortem examination. It is true that the physician may have had a belief as to the cause of death, but the circumstances under which death occurred warranted him in hesitating to give the certificate required by the ordinance of the city of Denver in this case. This being so, and the proofs showing conclusively that the body was not mutilated, and that the autopsy was performed in a decent and scientific manner, with due regard to the sex of the deceased and the feelings of all parties interested, I can not conceive what possible damages could be proved to a jury." *

The matter may be summed up as follows: An autopsy performed with the consent of the relative who is entitled to the custody of the dead body can never be questioned if properly performed. Such an operation, when performed under direction of law, is never subject to legal punishment, yet the existence of the two cases last examined should be a sufficient reason to convince the cautious practitioner of the advisability of always securing such consent when possible. Where consent is withheld, and the physician feels that a conscientious performance of the duty before him requires that a post-mortem examination be made, he should, in furtherance of his own safety, turn the case over to the coroner, or at least act under the direction of that officer.

*(To be continued.)*

**Pith of Current Literature.**

**Mental Healing, Regular and Irregular.—Dr. J. T. McColgan (St. Louis Medical Era, July), in an excellent article, says that the broad denial that the various systems of psychic healing at present in vogue are not curative, and the assertion that the results reported are fabrications, delusions, and frauds, are not entitled to be denominated skepticism, but gross ignorance. The instances are too many to be simply coincidences, and the standing of many of the psychic therapeutists too high to justify their being denominated frauds. That there are charlatans practising this new system goes without saying; but what great discovery has the world ever known that these harpies failed to seize upon as a means of exploiting their fellow man? Whether Liebault's theory of suggestion, which is the most plausible hypothesis is true or not, these facts are beyond all cavil:****

1. Through the mind the circulation can be controlled to a very great extent, the heart beats made to vary fifteen per minute on each side of the normal standard.
2. The temperature may by the same means be made to vary five to eight degrees on each side of the normal.
3. All the vegetative or automatic functions may be modified or increased in the same manner.
4. Pain may be arrested and total anesthesia, local or general, may be induced.
5. One function may be inhibited without interfering with any other; as by contracting the pupil of one eye, leaving the other normal; or contracting one and dilating the other.

Of course, all these can not be produced on every subject to their fullest extent, but a sufficiently large percentage can be so influenced to establish the fact.

* Cook et al. vs. Walley et al., 1 Colo. App., 163; 27 Pac. Rep., 950.
that there is a power in the mind which is capable of producing these results; and the failures are more probably due to our want of knowledge in exciting it to action than to the fact that some minds are destitute of the power. The writer has had several years' experience with suggestive therapeutics, and the fact stands out in bold relief in his experience, and this fact is that different minds require different methods to induce suggestion exercising any power over the physical processes of the organism. One will readily receive incidental suggestion by the administration of a placebo, but will ignore suggestion during hypnosis. Another, on whom neither placebo nor medicine will have any effect, will be perfectly amenable to hypnotic suggestion. Still another class will receive any kind of suggestion given in any manner whatever. One class will hold a suggestion for a longer period than others; and this class is not the one most readily influenced, but the reverse. The failure to make a suggestion effective arises from a failure to command the subjective attention of the patient, and one method will attract this attention when another will fail. Disease is largely due to morbid self-suggestion arresting the natural resistance offered by the organism to deleterious substances. It is the natural function of all living organisms to throw off deleterious matters, to repair waste tissues and injuries of every class; but if all the force of innervation is concentrated on the effects or on anything else whatever, these functions will be ill performed or not performed at all.

As a very marked result of psychic therapeutics take an anemic or chlorotic girl about the period of puberty. Here the whole power of innervation is expended on the generative sphere. The sexual organs, just maturing, command the exclusive attention of the organism, and digestion and assimilation suffer. Now, by distracting this unconscious attention from the sexual organs by suggestion, the hyperesthesia of the sex centre is relieved; the innervation thus liberated goes to increase nutrition, and the patient rapidly recovers. In the author's experience these cases are invariably relieved by suggestion in one sixth of the time that is required under the most favorable circumstances with tonics.

What is termed "magnetism" is suggestion enforced through the sense of feeling or touch by stimulating the peripheral nerve endings. This is a more powerful nerve stimulant than any we have in our materia medica, and is wholly mechanical in its nature. You take a healthy, robust individual of either sex, confine him or her on a couch, and tickle the bottoms of the feet for three hours, and you have a fit subject for a lunatic asylum. Hard or rough contact with these nerves does not produce this effect, but rather the contrary; sensation is deadened or obtunded instead of excited. Now, modify this tickling until it is barely perceptible, and a most delicious sensation is produced; and actual contact is unnecessary to produce it—atmospheric waves coupled with psychic suggestion is all-sufficient. Tickle a boy or girl until he or she can not control their visibleness and you may keep it up indefinitely by the mere motion of your fingers. Now, in what is termed "magnetic" healing you employ two forces synergistic, as we say of medicines, to each other: one psychical and one mechanical. The mechanical, to use a strong term, "presses the button and suggestion does the rest." In precisely the same way we often "press the button," with a granule, a tablet, or an "elegant," much-advertised pharmaceutical preparation, and then we give all the credit to the material thing we see and wholly ignore the force we don't see.

"Christian Science" is suggestion enforced by or through the emotion of religion; the dogma of the unreality of matter and the consequent unreality of disease not playing the slightest part in the cures, as the following paper will show. The author had a patient with torpid bowels which would only act after large doses of purgatives re-enforced by enemas. He was a materialist of the strictest sort, skeptical on everything from religion to science, and took pride in disbelieving everything he heard or read; one of these characters that would argue and dispute with a mile-post about the distance to the next town, even if he had never traveled the road before. After satisfying himself of his patient's physical condition, the author commenced a conversation in which he reversed the usual oration of the Christian Scientist. "Matter," he said, "is everything, and mind only the result of the transformation of material molecules of matter; without a material brain there can be no mind, and the creature can not possibly influence the creator. Now, I am going to convince you of this fact in a way that you can not fail to understand," and he took a phial from his case. "Here is an alkaloid from the most powerful purgative known to medical science; so powerful in its action that only one fifth of a grain is the maximum dose. I am going to move your bowels with this tablet tonight. Now, you concentrate your mind against it with all the power you possess and see if it does not act, notwithstanding your mental resistance." Dr. McCollan gave him one of Parke, Davis, & Co.'s sugar-coated placebos and he had three copious actions from his bowels as the result. Unknown to the patient, the doctor had concentrated the patient's attention on the alimentary canal; this innervation increased glandular secretion and peristalsis, with the natural result. Had the patient been assured that the doctor would move his bowels by operating through his mind, self-suggestion would have prevented the suggestion being entertained; but by this ruse self-suggestion was turned to the purpose it was desired to accomplish.

Osteopathy is suggestion emphasized by massage and manipulation. You might manipulate a patient for a week without his knowing that it was for the purpose of alleviating his disease, and there would be no more result than from any other exercise.

In all kinds of psychical therapeutics we must remember that the theory of the healer has nothing whatever to do with the results achieved; that the patient in reality cures himself, and the influence of the system only places him in that condition of passivity where natural processes have fair play and undisturbed action. From the author's experience in treating anaemia by hypnotic suggestion he is led to believe that there is a brilliant future for this treatment in that class of diseases where faulty nutrition is the dominant feature. Cell nutrition is one of the physiologic processes on which we have vague and perhaps erroneous views. When we come to fully comprehend the part which innervation plays in nutrition, when we cease directing our therapy so much to results and looking more at the cause, we may find it just as simple a matter to control the malnutrition which initiates consumption or cancer by suggestion as it is to arrest a headache or neuralgia.

Syphilis and Scrotal Cancer.—Dr. A. Patterson (Scottish Medical and Surgical Journal, August), in
paper read before the Glasgow Eastern Medical Society on Some Phases of Syphilis, relates the following case: A consultation was called in the infirmary one morning. Our worthy colleague explained, apologetically, that the case was simply one of sweeps' cancer, and that the consultation was only a formal matter. There was no dissentient voice. Operation was performed, and the part removed was sent as usual to the pathological department. After microscopic examination the disease was declared to be epithelioma beyond a doubt. When the wound was almost healed the disease reappeared and began to spread, necessitating a second removal. It had reached the healing line when it again opened up, and now adhesion to the testicle led to castration. This time everything went well so far that the wound was healed just to a point, and as my colleague was going off on his holidays, the man was dismissed. The patient belonged to the East End, and it so happened that in less than three weeks I was asked to see him. Once more the wound had spread, and I was requested to operate. It looked a hopeless business, however I did it, taking as wide a margin as possible. Like all the preceding operation wounds, it stopped ere the healing point was reached. Fairly puzzled, I had never known a case of epithelioma conduct itself in this manner, and yet the microscope declared it to be that "without doubt."

Risking a question, "Were you ever in the service, my man?" "Yes, sir, I fought through the Crimea." He was put on five grains of the iodide and five of the tartrate of potassium. The wound healed rapidly, and the man remained in good health for ten years, when I lost sight of him. Naturally, this case shook my faith in the microscope. There can be, I fancy, little doubt that many of the cases of so-called chimney sweepers' cancer, which have been operated on as such, were in reality tertiary syphilis.

Calomel in the Treatment of Conjunctivitis.—M. Poukaloff (Presse médicale, June 24th; Medicine, August) thinks that calomel will meet the same indications as nitrate of silver in ophthalmia neonatorum, for which the latter drug is considered almost a specific, and that it has not the same inconveniences. The conjunctive should be carefully cleansed with a solution of boric acid and then dried with tampons of cotton, and the calomel carefully dusted over the mucous membrane in a thin layer. The method is applicable among the poor, as it requires to be repeated but once a day, and in the vast majority of cases is followed by a prompt amelioration of the symptoms, the duration of many of the cases not exceeding seven days; and even in those that were chronic and severe, recovery has been noted in fifteen days. The author's observations are based upon fifty-seven cases of ophthalmia in which gonococci were noted in the discharge.

A Simple Method of Examining Stomach Contents.—Dr. W. H. De Witt (British Medical Journal; Maryland Medical Journal, August 5th) records the following novel device for securing a small quantity of the contents of the stomach for examination: "Take the long end of a largest size empty capsule; into this crowd or condense as much as possible of fine sponge, to which is attached a fine silk thread of sufficient length. The capsule is then closed and the patient allowed to swallow the same. After sufficient time has elapsed for the capsule to dissolve, the sponge is removed by the string.

The sponge will be found to have absorbed a sufficient amount of gastric contents for all practical purposes. In this way tests can be made for free hydrochloric acid, or, indeed, for anything else that may have been taken into the stomach. This method is original with me; I do not know whether others have used the same device or not. It will, I am quite sure, be found a very convenient and practical method. Several capsules prepared in the same manner and swallowed would furnish a sufficient quantity of gastric juice for any and every purpose."

A Case of Human Ruminations.—Dr. Luther C. Peter (Medical Mirror, August) records a case of ruminations in a boy nine years of age, and offers the following conclusions: 1. Ruminations is a neurosis, associated with a profound neurasthenic condition or idiocy. 2. It is, as a rule, associated with a diverticulum or dilatation of the lower end of the esophagus, but is primarily a stomach neurosis. 3. It may at times be hereditary. 4. It occurs more frequently in males than in females. 5. It is usually within the control of the will. 6. The prognosis as to cure is good.

Euphthalmine as a Mydriatic.—Dr. H. Darier (Clinique ophtalmologique, April; Therapeut, July 15th) reports that since he began to use euphthalmine for ophthalmoscopic examinations he has never observed any of the unpleasant symptoms so frequently met with after the use of other mydriatics. The patients have never complained of any inconvenience except a slight dimness. The same evening, the euphthalminized eye has always returned to its normal state. This agent is recommended to be employed in doubtful cases, where it is desired to ascertain if one has to deal with an iritis. If there is really iritis, atropine will have no ill effect; but if, on the contrary, the case is one of simple circumcorneal hyperemia, etc., one will have caused eight or ten days of paralysis of accommodation, whereas if dilatation has been effected with euphthalmine in a rapid, regular, and complete manner, quite as accurately a diagnosis could have been made without causing any of the inconveniences following the use of atropine. He uses one or two drops of a five-per-cent. solution.

The Ambulant Treatment of Fractures of the Lower Limb.—Dr. C. W. Cutheart (Scottish Medical and Surgical Journal, July) says that the expression "ambulant" does not exactly indicate the sense in which the "walking about" treatment of fractures is intended to be taken. It does not merely mean that the patients are to walk about while the treatment of the fracture is going on. This would be true of almost all fractures of the upper extremity or of those of the lower limb if the patient were using crutches, but it means that the broken limb is itself to be used for walking upon during the time that the union is taking place. The mechanism by which this can be accomplished will be easily understood, especially by those who know the principle of Thomas's knee splint or who have studied the various ways in which an artificial limb can be made to take its "bearing" at some part of the limb above the face of the stump. In all these cases the weight of the body is transmitted from the ground past the tender area to some point above. The "bearing" point, for instance, might be the enlarged portions of the tibia and fibula below the knee, the muscles of the thigh as they thicken upward toward the hip, or the tuberosity of the ischium and neighboring parts of the pelvis. In
the case of Thomas's knee splint iron is used, and in artificial limbs the material is generally wood. In either case the necessary fitting must be carried out by a skilled workman. The great advantage, however, of plaster of Paris is that, since it is put on while soft, it adapts itself perfectly to the part on which it is to have a "bearing," and yet, after it has set, it is strong enough to transmit the body weight, and will also last sufficiently long for the healing of the fracture. It is at the same time very cheap and requires no more skill in application than may be expected from any member of the medical profession.

There are many different ways in which the details of the ambulant treatment may be carried out. The method has been applied to fractures of the thigh as well as to those of the leg. Let us take the case of simple fracture of one or both bones of the leg in the lower two thirds without any very marked shortening. Although many would apply the "ambulant" dressing at once, the author would prefer to wait until the swelling had subsided. Massage, in the form known as "effleurage," will greatly hasten this, and in two or three days the parts will be ready for the permanent splint. During the interval the injured limb must of course be steadied with a "box," "Cline," "Mackintosh," or any other splint which the surgeon may be accustomed to use.

When the limb is ready the surgeon will require—

1. Plaster-of-Paris bandages. The best material for these is open bleached gauze, such as is in constant use in surgical wards for packing cavities or for making artificial sponges with, etc. "Butter-cloth" answers very well. The starched gauze called "erioline," often recommended, is not nearly so good as soft white absorbent gauze, and a closely woven bandage, whether absorbent or not, is useless for plaster bandages, as any one will find who tries it. The simplest way to get ready a number of bandages is to take a "piece" of the gauze about three yards in length and roll it up evenly on a table, then with a sharp knife cut it into sections some three inches and some four inches in breadth. It will be well to have at least about eighteen of each size ready. They have next to have the plaster of Paris worked into them. Take a quantity of freshly baked plaster of Paris in a bowl; spread a newspaper over a flat table or board; now lay one end of the bandage on the table, and having sprinkled plaster freely over it, rub it in with the hand; roll up loosely with the fingers the part of the bandage thus treated, and proceed with a new part, which is to be in turn rolled up. Repeat this until the bandage is finished. Lay it carefully aside so as not to shake out the plaster, and proceed in a like manner with the rest.

2. A pad of cotton wool an inch and a half to two inches in thickness, to fit under the sole of the foot. This pad is the special feature of the method. When the patient's weight is put upon the splint this pad becomes compressed, and the pressure thus prevented from reaching the sole of the foot is carried up the sides of the splint to the "bearing" point above the seat of fracture. In other words, the patient walks on the "bearing" point.

3. Flannel or domet bandages, some spare cotton wool and gauze.

Two assistants are required in order to hold the leg in position. Some think that the foot should be steadied with the fingers of the assistant; some prefer to apply pieces of gauze, one to lift the heel, one to provide extension. These are afterward included in the bandage. The surgeon begins by fixing the pad of cotton wool to the foot with a domet bandage; in so doing be may with advantage fill up the hollow below the malleolus with cotton wool so that the plaster bandage can not carry the malleolus upward when the patient is walking. The domet bandage is then carried evenly up the limb and extends a little beyond where the plaster of Paris is expected to come. This bandage is to act as padding; some apply the plaster of Paris next the skin, and some put on a thin layer of wool; the flannel or domet bandage, however, seems to the author preferable to either of these methods. When the limb has thus been prepared for the plaster-of-Paris bandages these are placed in a pair of water, one or two at a time. Each must be laid vertically—i.e., with one end of the roll at the bottom and the other toward the surface—to allow the air bells to escape as the water sinks in. As it is taken out, the bandage is gently pressed to get rid of the superfluous water, and it is then ready to be applied to the limb, which is now being held in position for the purpose. Experience has shown that the plaster case is especially apt to give way on the sole and at the ankle, and at these places an extra number of turns must be put on. The sole is thickened by bringing the bandage many times backward and forward from the toes to the heel with occasional turns round the foot to keep these in position. When this part has been well begun the bandages should be carried up the leg, taking care to avoid creases and wrinkles in the deeper parts, and especially just below the knee, where the weight is to be borne. As the knee is to be left free to bend, the bandage must either stop short of the back of the knee or, if carried up there at first, it must be afterward cut away behind; the first method is easier and is quite as efficient as the second, although some prefer the latter.

The bandages are then laid on layer after layer until it is about nine ply thick all over, and about twelve or fifteen at the ankle and on the sole. The splint must be as tough and light as possible, therefore the various layers should be rubbed in upon one another, but no extra plaster should be added beyond what is incorporated in the fibre of the gauze—i.e., no masses or lumps of plaster between the layers. When the required thickness has been reached the surgeon should see that everything fits nicely about the knee; there should especially be no pressure on the popliteal space, the color of the toes should be looked to. If necessary the bandage can be pulled outward from the popliteal space and pressed in to fit the bones exactly, while it is still soft. In about ten minutes the plaster will have set, but it is much better not to put any strain upon it until it is quite dry. It is therefore safer to keep the patient in bed for twenty-four hours, leaving the splint exposed to the air and hastening the drying with hot water bottles. At the end of this time the patient gets up and begins to walk, using his leg, now inceased in the splint, for the purpose. At first, of course, he can only limp and needs support, but before long he can move about with comparative freedom. A cover of felt or leather should be made to protect the case as much as possible from tear and wear. The weight of the appliance, the rigidity of the foot, and the increased length of the limb caused by the foot pad, all taken together, make some patients despair at first of being able to walk with the splint; but in a few days they get used to the new condition of things, and in about a week they can move about with surprising activity and freedom.
The splint is allowed to remain on until the fracture has had time to consolidate. When it is removed the condition of the limb is carefully examined, and if union has taken place the patient is encouraged to use the leg more and more.

The results obtained by this method have been most satisfactory, and perhaps one of the best proofs of this may be found in the fact that it has been largely used in America.

Resection of the Cervical Sympathetic in Glaucoma.

—Dr. James Moore Ball (Interstate Medical Journal, July) translates in extenso the article on this subject by Professor Thomas Jonneco in the Wiener klinische Wochenschrift for May 4th. Professor Jonneco concludes his article thus:

"The operation may be divided into four stages:

1. The cuttinganeous incision begins at the upper angle of the inferior maxilla and extends along the anterior border of the sterno-mastoid.

2. The anterior border of the sterno-mastoid muscle is freed. After cutting the skin, superficial cervical muscles, and superficial fascia, the anterior border of the sterno-mastoid is freed by means of a grooved director and the muscle is drawn outward and backward by a retractor; by a grooved director the deep layer of the parieto-neurotic sheath of the muscle is cut and then a second retractor is used on the inner lip of the wound, to draw the larynx inward. This brings the operator to the bundle of vessels and nerves.

3. The identification, separation, and excision of the superior cervical ganglion. After the anterior wall of the vascular bundle has been cut, one aims to draw the internal jugular vein outward and the internal carotid artery and vagus nerve inward by means of retractors. In the space thus made one finds the superior cervical ganglion easily; then by means of the grooved director the deep layer of the carotid sheath and the prevertebral fascia are opened. Isolated by means of the director and seized with forceps, the ganglion is followed from below upward. Then by means of the index finger it is carefully separated from the surrounding structures and all afferent and efferent fibres are cut by means of blunt curved scissors. When this is accomplished, the ganglion is attached only by the nerve trunks which forms its continuation above; a strong pull is made, and the ganglion is torn out. A cut is made below, and the excision is completed.

The operation described makes the complete removal of the ganglion possible; it is bloodless, and permits the fibres of the superior cervical plexus and the external branch of the spinal accessory nerve to be preserved.

4. Closure of the wound is divided into two steps: first, the border of the sterno-mastoid is united to the deep cellular tissue by means of three or four catgut sutures; the superficial part of the wound is closed by means of fine catgut. The wound is not drained.

The bilateral operation can be made in fifteen minutes. The results of the operation are striking; the epigastric is removed on the sixth day. Union is ideal if an aseptic operation has been made.

After the operation one observes congestion of the conjunctiva of the eye, the nose, lacrimation, considerable nasal secretion, heaviness of the head, all of which phenomena immediately disappear on the first day. The remaining effects upon the eye are contraction of the pupil, sinking of the eyeball in the orbit, drooping of the upper eyelid, and narrowing of the palpebral fissure.

"The therapeutic results are an immediate reduction of intraocular tension; there follows immediately, or within a few days, an improvement in vision, which increases from day to day. The periorbital pain and headache disappear. Frequently after the operation these patients complain of a heaviness in the head, which is probably to be attributed to the removal of the ganglion producing congestion of the brain, which should not be confounded with the glaucomatous pain. In many cases a slight dysphagia appears after this operation, and during chewing there is pain in the cranio-mandibular articulation, which are unimportant symptoms, as they soon disappear completely.

"In conclusion, it is clear to me that the following propositions are true:

1. The importance of the cervical sympathetic in the production of glaucoma, with the exception of the hemorrhagic form, is evident from these operations.

2. The sympathetic nervous system of the eye is continuously or temporarily irritated from the centre, or from a centre in the trunk of the sympathetic of the eye.

3. The resection of this ganglion through which all these fibres pass paralyzes them and annuls all ocular effects depending upon them.

4. One can argue about the mechanism of post-operative hypotonia, but the fact remains undisputed.

5. The best results are to be expected in those cases in which inflammation and irritation are not present or are not strongly marked.

6. Since the undertaking is by no means serious, one must attempt this operation in all forms of glaucoma, even in those accompanied by severe pain, cases of absolute glaucoma, where the pain has a tendency to disappear after the operation. The improvement of symptoms occurs at once after the operation or later; in all cases it is progressive.

7. This operation can be successful even in those cases in which, in spite of previous iridectomy, the disease progresses—i. e., in all cases in which the well-known operation guarantees no effect.

8. The occurrence of Basedow's disease and glaucoma at the same time, as in one of our cases, speaks for the influence of the permanent irritation of the cervical sympathetic wholly or only partly upon the occurrence of glaucoma. The resection of the cervical sympathetic curts Basedow's disease, a disease caused by the permanent irritation of these nerves. The removal of these nerves brings about the disappearance of these disturbances."

The Relation of Chronic Nephritis to Malarial Disease.—Dr. C. W. Larned (Johns Hopkins Hospital Bulletin, July), in a paper on Chronic Malarial Nephritis containing a minute report of a case, says that the conclusions to be drawn from this and other cases already on record, especially Thayer's and those of Kelsch and Kiiener, are: 1. Certainly in some localities malarial fever should be given a prominent position in the etiology of chronic as well as of acute nephritis. 2. In all cases of malarial fever the urine should be closely watched. 3. A blood examination should be made in all cases of nephritis occurring in those who have visited or lived in a malarial district, as it often happens that the severe grade of nephritis resulting may mask entirely the clinical picture of malarial fever.
Arsenite of Copper in Cerebro-spinal Meningitis.—Dr. Louis Kolipinski (Maryland Medical Journal, July 29th) records a series of cases consisting of three children and one adult in which the following routine treatment was successfully used: 1. Quiet, by excluding, as much as possible, persons, light, and sound from the sick-room. 2. A simple milk diet, with drinking water whenever desired. 3. Daily movement of the bowels by enema or castor oil. 4. The arsenite of copper for the first and second days every half hour while patient was awake; with improvement in the symptoms the intervals of dosage were prolonged to every one or two hours on the third day, every two or three hours on the fourth day, till with apparent convalescence the remedy was discontinued. In addition a tepid bath was recommended should the fever rise suddenly and high. For children the formula employed was:

\[ \text{R: Arsenite of copper} \quad \frac{1}{16} \text{grain; Distilled water} \quad 3 \text{ounces.} \]

M.

The phial to be shaken. One teaspoonful every half hour.

For adults:

\[ \text{R: Arsenite of copper} \quad \frac{1}{8} \text{grain; Distilled water} \quad 4 \text{ounces.} \]

M.

Shake the phial. One teaspoonful every half hour.

Stricture of the Esophagus from Corrosives.—Dr. W. J. Mayo (Journal of the American Medical Association, July 29th) thus concludes a paper on this subject read before the meeting of the American Medical Association: 1. Systematic sounding should be commenced in two or four weeks after the swallowing of a caustic substance. 2. Should the traumatism be severe, immediate gastrostomy will lessen infection and hasten cicatrization, sounding being carried on as before. 3. Non-dilatable strictures in the vicinity of the cricoid cartilage should be divided by external esophagotomy. 4. Stricture above the arch of the aorta may be safely cut by a combined internal and external esophagotomy. 5. Dense thoracic strictures are best divided by Öchsner's method, and, if necessary, divided by Abe's string saw. 6. Impassable strictures should be treated by retrograde dilatation. 7. A dilated stricture should be occasionally sounded for years, if not for life.

Peritonsillar Abscess and Rheumatism.—Dr. Frederick C. Cobb (Boston Medical and Surgical Journal, July 27th), in a paper read before the American Laryngological Association, as the result of an examination of forty-four cases, concludes that: 1. No causative relation could be proved to exist between rheumatism and peritonsillar abscess. 2. An acute inflammatory condition of the tonsil was found to exist in a sufficient number of cases to suggest that it might be the cause of the infection to the peritonsillar tissue. 3. A study of the pharyngo-maxillary space shows: (a) that its injection with wax on the cadaver may produce an appearance similar to the peritonsillar abscess as seen clinically; (b) that its distance from the surface of the palate may account for the depth of the puncture often needed in order to obtain pus; (c) that the cross action of the muscles covering the space seems a sufficient reason for the closure of punctures made into it; (d) that the supratonsillar fossa and the infratonsillar space offer the surface for puncture most free from anatomical obstruction; (e) that puncture anterior to a plane passing through the posterior pillars can not injure the great vessels if the knife be kept at all times anterior to such plane; (f) that the space is divided into two cavities by a septum formed by the styloglossus and stylopharyngeus muscles. This in most cases protects the great vessels from purulent infiltration. Failure of this septum to act explains the cases cited by Bosworth where pus passed along the great vessels into the mediastinum.

Nature of Bartholinitis.—Columbini (Archiv für Dermatologie und Syphilis, 1899, xlvi, No. 2; Medical Review of Reviews, July 25th) has apparently settled two disputed points in connection with this disease: First, it is an affection of the duct, and never of the gland proper. Histologically there is a proliferation of the duct epithelia and a small-cell infiltration of the circumjacient tissue which is responsible for the abscess formation and for the tendency to relapse, which is so noteworthy here. Secondly, the pathogenic germ is always the staphylococcus, never the gonococcus. In this respect bartholinitis agrees with the other suppurative post-gonorrheal lesions; the action of the gonococcus appearing to pave the way for infection by the other germ.

As to therapy, Columbini believes in immediate excision of the gland as the only way to break up the pyogenic focus with its constant tendency to relapse.

The Use of Sanarelli Serum in Yellow Fever.—Dr. P. E. Archinard (New Orleans Medical and Surgical Journal, August) reports a series of eleven cases of yellow fever treated in hospital at New Orleans, and three mild cases treated in private practice, in the fall of 1898, with Sanarelli's serum received from Montevideo. An analysis shows that six out of the eleven hospital patients died, and in two of them the condition appeared to be aggravated by the serum. The five which recovered were of a milder type. The three private patients recovered, only one, however, showing the disease in any severity. Dr. Archinard remarks that from the foregoing cases, which limit his experience with the anti-amaryllic serum of Sanarelli as a curative agent in the human being attacked with yellow fever, he is forced to conclude that this agent, in his hands, has shown no curative powers whatsoever, none of the important and dangerous symptoms of the disease having been in any way mitigated, or prevented, by its administration. The hospital cases, it is true, were severe cases, and in some of them treatment was begun at so late a date as to preclude all hope. The patient's symptoms before and after serum injection showed so little change as to warrant the foregoing conclusion. In justice to Dr. Sanarelli, it must be said that he has never pronounced himself as believing absolutely that his serum was curative in the graver cases; he cautions all users of it that the whole subject is still under study and recommends that this serum be used early. This latter instruction is not always easy to follow, as a diagnosis can not always be made early. Indeed, in early cases of yellow fever it is difficult to say which are going to be severe and which not, and, judging by an experience in this city in the last two years, the great majority of cases are benign and get well under any treatment, and necessarily serum employed at random in these cases would be at a great advantage.

As regards the immunizing property of the serum in the human species, the author has no experience and can not speak with authority, but experiments per-
formed on smaller animals in his laboratory do not warrant him in entertaining a high regard for its immunizing power.

Book Notices.

We should judge this work to be the outcome and combination of the authors’ Pregnancy, Labor, and the Puerperal State (1895) and Obstetric Surgery. The only preface to the work is that which is said to be taken from the first edition.

The assertion is made that the book is practical; those who know the authors would expect such a work. There is no change in the lucidity and directness, the vigor of thought and diction, of the previous edition.

There is improvement in the mechanical part of the work; the illustrations are clearer, most of them, and the ink is less sticky. The previous edition was sadly marred by such defects.

The combination of the two divisions of the subject into one complete work was desirable; each was incomplete without the other.

The subject of the last chapter, ectopic pregnancy, is of such supreme importance that it might have been treated at greater length. True, the book is mainly the reflection of the authors’ opinions and experience; but this is insufficient for the elucidation of such a theme. We cannot agree to the old notion, so often expressed, that the life of the viable extra-uterine fetus is to be disregarded on the ground that most of those which have been extracted alive have been puny and deformed.

The mother’s life may be the more important, at least we may think so, but, as we can not foresee the future of the child, our plain duty is to take every precaution to husband its vitality and start it on its career with as favorable conditions as possible.

The chapter on the normal puerperium is especially sound and wholesome.

The chapter on the pathological puerperium is rather dogmatic. Thus: “Puerperal fever, therefore, never endogenous in origin. It is always exogenous; that is to say, emanates from without.” Still, it is admitted that latent sources of mischief may be in the patient’s body at the time of parturition, and one cannot always prove that they have been aroused by activity of influences from without. We believe, in company with some very good authorities, that the exciting influence is occasionally from within.

One is here advised against early hysterectomy for puerperal endometritis. It would be interesting to know how many lives had been saved and how many lost by hysterectomy during the early days of the puerperium, and whether those which have been saved would not have been equally safe without the operation. In other words, hysterectomy during the early days of the puerperium, when septic endometritis is pronounced, will rarely prove a life-saving measure. It does not reach far enough, and it is well to throw upon a tendency to perform an operation which can seldom be justified.

It is proper to refer to the influence of the authors in urging the study of pelvimetry, which is well accentuated, together with a clear résumé of the subject of asymmetry of the pelvis, in the chapter on dystocia.

On the use of the forceps the teaching seems to be traction, and traction only. That depends, of course, upon the operator. The pendulum motion is often useful, and may be entirely harmless. No one was more dexterous with the forceps than the late Dr. Isaac E. Taylor, but he did not hesitate to make use of this motion when occasion required.

The conclusions reached in this study seem to be that alcohol has no value either as a food or as a stimulant to muscular or mental work; that in normal health alcoholic beverages “are entirely unnecessary, and therefore do no good”; on the contrary, they often lead to inebriety, crime, and degeneracy; “that alcohol as a remedial agent might be forever banished from the physician’s armamentarium of drugs without in any way lessening his efficiency in combating disease”; that it is difficult to say which is the worst, spirits, wine, or beer, but all are bad; that the ordinary adulterants are practically harmless.

The author believes that if the consumption of alcoholic beverages were absolutely prevented the millennium would be in sight, and suggests a campaign of education to bring about such a result. He admits, however, that the statements in the school text-books are often inaccurate and exaggerated.

It is hardly necessary to add that the statements of our most authoritative physiologists are, to say the least, much less positive than those found in this book.

We said of the first edition that, while it gave a fair summary of the hay-fever question, the author’s observations upon the subject of treatment were not convincing, for the same measures advocated by him had quite failed to give equally good results in the hands of others. After looking over the present edition, we see no reason to alter our previous opinion. In it the author has enlarged the text so as to include the special treatment (according to his own ideas) of the various types of hay-fever cases. The section on bibliography has also been brought up to the date of publication.

Orography. No. 5. The Gouldstonian Lectures on the Pathology of the Thyroid Gland. By George R. Murray, M. D., of London. [Reprinted from the Lancet.]

MISCELLANY.

The Use of Separate Beds for Married Couples.—In an article on the Bedstead, one of the last published by Lawson Tait (Birmingham Medical Review; Canadian Journal of Medicine and Surgery, August), he says that "the additional comfort obtained by every English man and woman on a visit to the continent, when they found in their bedrooms two snug little single bedsteads placed side by side, made no impression till about ten years ago, when a few venturesome islanders began to dare the breath of scandal by having separate beds. There can be no doubt that this was the reason why the improvement was resented, for to this day the proof of the worst that can be circulated concerning a married couple is that 'they occupy separate rooms.' The use of separate beds was, and is to some extent still, regarded as almost as scandalous. Yet in all the best homes in our country each bedroom has attached to it a 'dressing room,' with a single bed in it, and by this a great increase in comfort and health is attained. Now that we know that consumption is a disease communicated from one to another by contact and breathing the air already breathed by the consumptive, the hygienic precaution of separate beds ought to receive some public recognition. For centuries the Italian physicians have taught the possibility of the disease spreading from husband to wife, and from one person to another, when a tainted and a healthy person have occupied the same bed. There are doubtless many other diseases of which the same is true."

An American Physician Decorated.—According to the Medical Times for August, the Shah of Persia has conferred the order of the Sun and Lion, the highest honor in the land, upon his physician, Dr. Holmes, an American, who has been established in Persia since 1874.

The Contagiousness of Bubonic Plague.—According to the Medical Times for August, an official report from the State Department from Alexandria, Egypt, expresses the opinion that the plague is not propagated by direct contact. There is no report of repeated cases in the same house. Immediately upon the sending to the hospital of individuals suspected to have the plague, all those who have been allowed to approach them, and especially those who have inhabited the same houses, are sent to a lazaretto outside the city. No suspected case has broken out among those who are known to have been in direct contact with individuals now down with the disease.
When "that no Therapeutics: said physical without "Rontgen to it by Bacon, who called it 'a conjunctural branch of the natural sciences.'

"Despite the enormous mass of positive data accumulated during the latter half of the present century—i.e., during the most brilliant period of medicine—the latter still occupies the position of which Virchow wrote in his salutatory editorial (Archiv für Pathologie und Therapie): 'Therapeutics must rise from its empirical standpoint; cultivated by practical physicians and clinicians and combined with pathologic physiology it must be elevated into a science, which up to this time it is not.' This was written fifty years ago, and it is but too true to-day!

"The reason is self-evident. Therapeutic problems involve so many uncertain and indefinite premises that deductions from them must be equally inexact, and therefore unscientific. Nevertheless the search after positive data must continue in order that a medical art may be constructed upon a scientific basis. Such a therapy is now in process of evolution in the modern development of the hygienic, dietetic, climatic, and hydriatic management of patients, as illustrated in typhoid fever among the acute and phthisis among the chronic diseases."

Congenital Absence of Both Eyes.—Guerrant (Archives of Pediatrics; Atlanta Journal-Record of Medicine, August) reports the case of a primipara at full term who gave birth to a male child with congenital absence of both eyes. There was no trace of a globe in either orbit. The orbital fissures were about one fourth of an inch in length. There was no orbital enormity, and the forehead was not high. In other ways the child was normally developed.

Action for Damages for X-ray Burn in France.—Treatment for July 27th thinks that the following case may perhaps bear recounting, owing to the satisfactory result: Mme. Mochez, a young lady of Paris, recently brought a suit for five thousand francs damages on account of an alleged X-ray burn. The plaintiff had an affection of the thigh which the doctors advised should be skiaographed. The thigh was exposed three times without protection, with a total duration of sixty minutes.

Dr. Bardet, one of the witnesses, testified that burning would result in rare instances from the use of the Roentgen rays. Everything depended on the patient's physical condition. He maintained that if the doctors were made responsible for such accidents they would be obliged to renounce the use of the X rays. The medical man was acquitted.

Verbum Sapienti, etc.—We quote the following from the Plexus for July: A contemporary gives as a valuable hint the following: 'The best way to keep well is to remain in good health, and the best remedy for all ills is to avoid sickness.' It further tells us that "anybody who will observe these simple rules will never need a doctor."

When the laity, says the Plexus, become wise enough to observe these simple (?) rules, what is to become of the doctors? Let's not think about it. Let's live in hope.

Kerosene as a Mosquito Exterminator.—In view of the scheme for checking malaria by killing with kerosene the mosquitoes that harbor the malarial parasite, the Journal of the American Medical Association for August 5th states that a successful test of this method has been made in Italy. The water tank of an Italian villa was found to be swarming with culex larvae estimated at four or five hundred to the bucketful. Ten drops of kerosene added to the bucketful killed them all in twenty minutes, and a few teaspoonfuls sufficed for the whole tank of three hundred cubic feet capacity. At this proportion quite large ponds or even marshes may be coated at very slight expense.

Juvenile Cigarette Smoking in England.—According to the Lancet for July 29th, England, as well as this country, has its troubles from juvenile cigarette smoking. That Lancet says that the Local Government Chronicle of July 22d reports that the cigarette-smoking juvenile troubles some of the members of the Bridport town council a good deal. The question of excessive smoking among youths was gravely discussed at the last meeting of that body, when, says our contemporary, Alderman J—wanted the town clerk to look into the matter with a view of seeing whether the council had any authority to deal with it. The town clerk, as might have been expected, explained that he did not think there was any law that enabled them to deal with the subject. It might be coarse and rather strong-smelling tobacco, but none the less wholesome. Councilor S—said he should like to propose that the whole of the council discontinue smoking in order to set a good example, whereupon the mayor asked him if he was a non-smoker. Councilor S—: Yes. The mayor: Then don't restrict others. The matter was then allowed to drop, but, says the Lancet, we can not resist referring Councilor S—to the oft-quoted lines from Hudibras concerning those who "compound for sins they are inclined to by damning those they have no mind to." Has Councilor S—no frailties? asks our contemporary.

Colonial Sanitary Administration.—The Army and Navy Journal for August 5th says:

"In presenting some of the following considerations we shall also be giving a good lesson to that noble army of critics at home who are as wise in all matters colonial as they are in the conduct of a war. Their cool assurance will, however, scarcely be affected by the knowledge that the United States may well be pardoned a few mistakes if England, after generations of colonial experience, is still groping in the dark on many points of vital importance. Compare our vigorous work at Santiago and other yellow-fever districts with this state of affairs in India as outlined in the Civil and Military Gazette, of Lahore, India, which says: 'The last mail brings with it the text of Mr. Chamberlain's speech relating to the establishment of the London School of Tropical Medicine, which is undoubtedly one of the most crying needs of our empire.'

"This it proves by showing that in the recent Tirah campaign, while there were only a thousand admissions to hospital from gunshot wounds and other injuries, there were eleven thousand admissions to hospital from fever and dysentery; and that while there were one hun-
dread deaths from wounds and injuries, there were nearly six hundred deaths from diseases of the tropical kind.

'IT is certainly time,' proceeds the Gazette, 'that something was done to put some order and system into the study of a question which is of such vital interest to the empire. No nation, certainly, but the English would have been colonizing for the last three hundred years and ruling in India for the last hundred and fifty years without making a special study of the particular conditions of the climate in which it was called upon to rule. At the present time no ordinary practitioner in England has the faintest idea of the nature or treatment of malaria, and the ordinary medical man on his arrival in this country is in a similar condition of happy ignorance. It is time that this state of chaotic indifferency should stop.'

'Though the colonial secretary is apparently hopeful that through the labors of science the disease will in process of time diminish, the Gazette expresses the fear that Mr. Chamberlain is oversanguine, and holds that a disease that is in its nature a necessity of the climate stands on a different footing from one that is merely epidemic. It ridicules as a Utopian dream Mr. Chamberlain's belief that some one will find a cure for malaria, and for the fevers desolating the colonies and dependencies in many tropical regions, and that 'better sanitation, better nursing, better medical attendance, may gradually reduce the tale of victims, until Englishmen may live almost as safely in the Deccan or in the Soudan as in Leicestershire.'

'That this contention of the paper is sound, it goes on to prove by declaring that the spread of civilizing agencies in India is only increasing the death-rate from malaria. This startling state of things it attributes to the spread of canal irrigation, which is adding stability to the conditions that produce malaria.

'We refer,' says the Journal, 'to England's troubles less with a desire to criticise her capriciously than to soften the blows our own patriots aim at their government for not knowing the business of colonization at once. The contention of the skeptic that even omnipotence can't make a three-year-old stepper in a minute may, after all, be susceptible of easier proof than that this government can master in less than a year problems that are to-day staggering Great Britain, though she has had a century and a half experience in dealing with them. What will the critics of our government say when, against the work accomplished at Santiago, where its lowest death-rate was attained this year, we place the recent declaration of the Indian Medical Record in the editorial opinion that Bombay and Calcutta are doomed cities, because of the practical impossibility of ever getting their sanitary conditions into reasonably good shape?'

A German School for the Study of Tropical Diseases.

—According to the Journal of the American Medical Association for August 5th, the German Government is about to establish at Hamburg a school for the study of tropical diseases.

Medical Education in Kentucky.—The State board of health of Kentucky, in a circular dated August 1st, gives notice that it will hereafter refuse to recognize, as a basis for certificates to practise medicine, diplomas from any medical college which does not, in good faith, comply with the requirements of the American Medical College Association, the American Institute of Homoeopathy, and the American Eclectic Medical College Association, respectively, both as to preliminary education and as to the four years' course of study. This means that no school that graduates three-year students will be recognized in the State hereafter. The board provided an examination for three-year graduates of the present year, as many of the students had attended such schools in ignorance of its advanced requirements, but found this course unsatisfactory, a large percentage of the examinations indicating incomplete preliminary education as well as imperfect medical training. This standard for the State of Kentucky was made and promulgated in 1891, to take effect this year, but notice of it is again published that schools patronized by Kentucky students and future graduates expecting to practise in Kentucky may fully understand the requirements.

Colloquing Bacilli.—Dr. Dunbar Roy, of the Atlanta Journal-Record of Medicine, assures us that he recently overheard the following conversation:

Typhoid bacillus: 'Will you be with us next summer?'

Bacillus coli communis: 'Can't say; my movements are very uncertain.'

The Dolomol Compounds.—Dr. Thurston G. Lasuk (Journal of Cutaneous and Genito-urinary Diseases, August) reports that he has used these compounds in more than a hundred cases of skin diseases. He has found dolomol-acetanilide (twenty-five per cent.) useful in varicose ulcers and particularly in chancroids. He has used dolomol-resorcin (ten per cent.) in seborrheal eczema of the face and body, in seborrheoa oleosa, and in acne with excellent results.

Dislocation of the Head of the Humerus and its Reducibility.—The International Journal of Surgery for July publishes an abstract of a paper read by Dr. Thomas H. Manley at the recent meeting of the American Medical Association in which the author says that irreducibility is not very uncommon, but sometimes an arm which can not be reduced immediately after injury may, on the following day, or even later, readily return on slight manipulation, or spontaneously return during the movement of a patient in bed. The period when reduction should be undertaken is an important one. That we should insist on immediate reduction in all cases is, no doubt, a mistake, and may result in serious consequences to the patient. Shock has been sustained, there may have been a free hemorrhagic effusion into the capsule or surrounding tissues with marked muscular spasm. The patient has suffered great violence, and why expose him to the risks of another fresh assault until the system has well revived from the first? Boyer reminds us that we need have no fear of trouble from the pathological changes that follow, because the parts are in a state of "stupor" for some time after displacement, and, moreover, Lund, of Boston, says that "a luxation of less than two weeks' standing is as easily reduced as a fresh one.'

Osteopathy Illegal in Pennsylvania.—According to the Medical Record for August 5th, the Medical Council of the State of Pennsylvania on May 24th decreed the practice of osteopathy in that State to be illegal.

The Richmond Academy of Medicine and Surgery.—The subject for discussion at the meeting of August 8th was facial paralysis.

THE ANTHEMION.

By WALLACE WOOD, M.D.

I first noticed the anthemion form upon the under occipital lobe of a female human brain, presented to me by my much-lamented master and kind friend August Voisin, of the Salpêtrière, on New Year's day, 1896. While preparing the two separated hemispheres by the nitric acid and bichromate process, turning them over frequently, and watching with care that no distortion might take place, I one day observed sculptured quite plainly upon the left hemisphere a figure of three ovals or scrolls interlaced or interlying, and producing almost the exact appearance of the half of a well-known design that crowns nearly all Attic tombstones and Greek temples—the mystic flower of life in death the anthemion or "palmette."

As might be supposed, I did not look upon the matter seriously. I presumed that it might be a mechanical or vegetative accident and without physiological or psychological significance. Nevertheless I made a note of it, and two months later while engaged in the preparation of a series of the brains of cattle, I was most certainly surprised, not to say startled, when I found that the under occipital lobe, which in bulls and cows is very large, and is indeed the only occipital lobe, presents to the naked eye an appearance which it seems to me can be nothing else and nothing less than the famous anthemion entire, right half on the right hemicerebrum, left half on the left hemicerebrum, the anthemion, the immortal flower, stamp and symbol of the life of the race. My mind reverted at once to the "sacred tree," the arbor vitae, with its mystic flower the anthemion on the Assyrian monuments, where also, singularly enough, it is often figured as battered by rampageous bulls.

The question then arose, Could the ancient Egyptians, Assyrians, and Greeks, with whom the anthemion was in constant use as a sepulchral device, have known of this analogous appearance upon the under occiput of men and cattle? The answer is No. The well-known sepulchral design and symbol is in its origin distinctly floral and not animal or cerebral; it is derived probably from the lotus or water lily, a plant which exhibits in striking clearness the "heart of the flower," that peculiar stamenate-pistillate interscroll formation by the function of which the life of a race is preserved from extinction, well taken as the emblem and guarantee of perpetual life on earth.

The anthemion or mystic flower of the tree of life as a sepulchral design originated in Egypt, passed to Assyria, and culminated in Greece, where it assumed two exactly opposing forms: one is the convex or male anthemion which, as a rule, crowns the Greek tombstone or Attic stile, which, we must remember, was in its origin a conic pillar; the other is the concave or female anthemion, a design plentifully strewn over all the Greek sepulchral vases. We rarely find the female anthemion on the sepulchral cone, and never the male anthemion on the sepulchral cup. We see indeed how fitly the convex or overbending flower crowns the cone, and how perfectly also the vulvalike or outrolling flower becomes the sacred or sepulchral chalice.

The sacred flower both in the convex and concave form has passed into civil architecture, and known as the palmetto, is one of the most common of the classic designs.
SUBCUTANEOUS TENOTOMY.

BIOGRAPHICAL NOTES.*

BY A. B. JUDSON, M. D.

In 1876 Dr. Louis Stromeyer (1804-1876) reached the fiftieth anniversary of his graduation in medicine at Berlin. The event was celebrated at Hanover. Mr. William MacCormac read the British address, which contained the following words: “Your discovery of a safe method of subcutaneous surgery forms an epoch in the history of our art”; and Dr. Little “made some remarks thanking Stromeyer for having consented to sit for a marble bust,” † which was presented to the college at London, where it stands “among those of the most eminent British surgeons.” ‡ “Stromeyer designated Dr. Little as the Apostle of Tenotomy, and ascribed to the visit paid him by Dr. Little the rapid diffusion of a knowledge of its happy results in Germany, France, and the United States.” § “Never was any great surgical operation, involving a vital principle of surgery, spread in less time over the globe, and with less resistance than tenotomy.”  

In 1829, at Hanover, Dr. Stromeyer “established a private orthopedic institution, and here, in February,

---

* Read before the American Orthopedic Association at its thirteenth annual meeting, New York, June 2, 1899.
† Medical Times and Gazette, London, April 22, 1876, p. 450.
In 1836† our late honorary member, Dr. William John Little (1810–1894), visited Dr. Stromeyer at Hanover and—"unknown to his nearest friends in London, who would, he feared, have tried to prevent him as they known of his intention," † and disregarding the advice of many surgeons, of whom "none gave him sleep or hope" ‡—submitted himself to subcutaneous tenotomy for the relief of talipes equino-varus of the left foot, "in which the sole was turned toward the opposite ankle," § the result of an attack of infantile paralysis at the age of four years. ¶ Up to the time of the operation he had worn instruments, "but could not walk any yards without pain." The result of the treatment at Hanover was satisfactory, and he was enabled "walk twelve miles with pleasure." ¶ "The benefit which he had received at the hands of Stromeyer laid him under a deep obligation, both to that surgeon and to society at large, to devote his energies to the extension of the knowledge of tenotomy among the other scientific men of the day." * In Berlin "his emphatic testimony to the success of Stromeyer's practice and the silent evidence of his own once deformed but now nearly corrected foot caused a revulsion of feeling in favor of subcutaneous tenotomy," † a method which was not practised in England until he performed the operation in London, February 20, 1837. † In 1839 he commenced the formation of the Orthopaedic Institution in Bloomsbury Square, since designated the Royal Orthopaedic Hospital," ‡ and the same year was published his well-known book Clubfoot and Analogous Distortions.

Our late honorary member, Dr. William Detmold (1808–1894), was born in Hanover, came to New York in 1837 and introduced orthopaedic surgery into this country. || Within two years after his arrival in New York he had made a hundred and eighty subcutaneous divisions of the tendon Achilles in cases of club-foot.  

At a stated meeting held on November 21, 1878, by the New York Academy of Medicine, by whose generous courtesy our meetings are held in these conven-
which now occupies an honored place in Woerishofer Hall of the academy’s library. Thanks were unani-
mosly returned to Dr. Little and Dr. Detmold, and the
former was elected a corresponding fellow in the follow-
ing year.*

It is evident that in current medical opinion Stro-
meyer was credited with having discovered subcutaneous
tenotomy, Little with having widely disseminated a
knowledge of it, and Detmold with having introduced
it into America.

It may be added that not a few of the advances
which have been made in surgery have been due to
a previous false conception of the dangers which might
follow the invasion of certain cavities and regions of
the body or the disturbance of certain tissues. In the
case of tenotomy Dr. Stromeyer was honored because
it was believed that he had discovered a safe method
of dividing tendinous structures whose fibres and
sheaths are now seen to accommodate themselves read-
ily to operative traumatism. His discovery greatly
stimulated the study and practice of operative ortho-
pedic surgery. It remains to be seen when mechanical
orthopaedic surgery will meet with a commensurate
recognition. A wider diffusion of knowledge may give to
it the precedence which now belongs to operative treat-
ment. In the matter of congenital clubfoot, for in-
stance, it is plain that tenotomy will decline in value
when it is generally seen that the affection is curable
by an early and patient resort to purely mechanical
means.

**GUNSHOT WOUNDS OF THE CHEST IN
THE SPANISH-AMERICAN WAR.**

*From the minutes of the academy and the statements of ex-Pre-
ident Dr. S. S. Purple.*

**NOTES ON TENOTOMY.**

By Henry S. Greenleaf,

First Lieutenant and Assistant Surgeon, U. S. Army.

To get our sick and wounded into well-established
hospitals for their ultimate treatment and away from
the danger of contagion and other unhealthy surround-
ings, during our late war with Spain, required frequent
transfers, which have left some very unsatisfactory and
unconnected data for records, and might readily have
led to erroneous conclusions regarding prognosis or
treatment when considered under the conditions of war.

There is much that would be instructive and valuable
to know if we could connect the history of these cases
from beginning to end, as they progressed in the differ-
ent places where they were under treatment. For this
reason there is probably much misapprehension con-
cerning the nature of many of the gunshot wounds of
the chest, especially among those under whose care they
came soon after the injury was received. Several cases
that looked most encouraging shortly after being
wounded later developed serious complications.

Noting one or two such instances, I began to collect
the histories of as many cases as I could find recorded
by the different surgeons who had attended them. I
have been able to collect the records of twenty-four
cases as they were sent in separately to the surgeon-
general’s office by these surgeons, and of these cases, fif-
teen recovered without complications; three had hemo-
thoraex, without going on to foration of empyema; and
six developed hemothorax, which eventually became
purulent and required operation. One out of this lat-
ter number had peritonitis and died.

The histories of these cases were as follows:

**CASE I.—Winslow Clark, Company G, First Volun-
teer Cavalry.** Wounded July 1st by a Mauser bullet,
which perforated the left scapula through the infra-
spinous fossa, the shoulder blade, and an inch from
the spinal border. No exit. The probable course
of the bullet was downward and forward into the chest.

There was some haemoptysis and fever. No vomiting
of blood. The hemothorax was quite extensive, and
was relieved by thoracentesis, performed a week after
the injury was received. He recovered without fur-
ther complications.

**CASE II.—Harry Mitchell, Company C, Seventh In-
fantry.** Wounded July 1st by a Mauser bullet, which
entered over the spine of the left acromion pro-
cess of the scapula, passed through the apex of the left
lung, mediastinum, and right lung, and having its
wound of exit in the second interspace, right nipple
line. There was at no time any haemoptysis, though a
slight hæmoptysis developed on the right side with
some dry cough. He at that time had fever that was
promptly controlled by quinine, and his spleen was
greatly enlarged. The recovery from his wound was
complete without surgical interference.

**CASE III.—Lieutenant Nair, Eighth Infantry.** Was
wounded at the battle of El Caney by a bullet which
passed through the left chest, of the exact location
of which I am not informed. There was considerable
haemoptysis immediately after the wound was received,
which persisted for a few days. The wounds of exit
and entrance healed. Later, at the General Hospital
at Fort Monroe, there was found flatness over the left
chest, with all the signs of an effusion into the pleura.

This was aspirated off and a large quantity of sero-
sanguineous fluid withdrawn. Later this was repeated
with the same result. Eventually signs of supraem-
pyema were present, so an incision was made and a large em-
pyema opened into. Recovery followed this operation.

**CASE IV.—John B. Senica, Company G, Twenty-
second Infantry.** On July 1st was wounded by a
Mauser bullet, which entered the back, just below the
angle of the left scapula, passed up through the lung,
neck, and jaw, and emerged through the alveolar process
of the right bicuspid tooth. Both wounds healed by pri-
mary union. Just after the wound was inflicted he had
profuse haemoptysis, which lasted for a few days.

There was loss of power of left arm, which disappeared
gradually, numbness and tingling in the fingers, and
desquamation of skin on the left hand. While on the
Relief his temperature was normal, condition generally
good, and on the twentieth day after the injury he was
allowed to sit up for a short time each day. When ad-
mitted to the Long Island College Hospital his tem-
perature was 102° F.; there was considerable dyspnea.
On August 2d thoracentesis yielded nothing. On August 23d the symptoms demanded a more radical operation, so two inches from the seventh rib were excised and eight ounces of pus removed, with fragments of disintegrated clot. Recovery followed this operation.

Case V.—Report of a case at Long Island College Hospital. Rough Rider. Wounded on July 1st by a Mauser bullet, which perforated the right forearm and the arm, fracturing the humerus, and entered the chest just below the axilla, emerging between the seventh and eighth ribs, near their vertebral attachment, causing a compound fracture of the eighth rib, right side, at its angle, and lodged beneath the skin. On the 27th he was admitted to the hospital, with fever ranging from 100° to 103° F.; had a harsh, dry cough and great dyspnea, with signs of an effusion in left pleura. Thoracentesis on July 1st yielded one pint of a serosanguinaceous fluid. On July 22d an incision over the eighth rib recovered the lead core of the bullet; this was extended into the pleura and two pints of purulent fluid escaped. On August 10th the seventh and eighth ribs were resected and a large quantity of débris, clot, etc., was removed, and the jacket of the bullet was found and removed. Patient recovered.

Case VI.—Arthur W. Fairbrother, Troop C, Third Cavalry. On July 1st was wounded by a Mauser bullet, which entered just below the middle of the left clavicle; no wound of exit. There was hæmoptysis, which subsided after the first few days. Soon after this there was an irregular rise of temperature with the beginning signs of an effusion into the right pleura, with a return of the bloody expectoration. On admission to the Relief, about July 12th, he had a large effusion in the pleura. The wound of entrance was not completely closed and discharged a dark bloody fluid on coughing. The sputum was thick and suggested a pneumonia, temperature very high, and great dyspnea. Paracentesis was performed about July 20th, and about three pints of a pure dark-red colored fluid drawn off, after which there still remained a large collection of material in the pleura, and the patient improved slightly, but only temporarily. On July 27th he was admitted to St. Peter's Hospital, Brooklyn. The wound had closed and the patient exhibited the same symptoms as above in an exaggerated form, the pleura having filled up again. An exploratory puncture was made and an empyema was found to have developed, for which reason the resection of a rib was necessary. This was done, posteriorly, and a large quantity of pus, clotted blood, and exudate was removed and an unsuccessful search for the bullet was made. The discharge was copious for a long while, but gradually diminished, and the patient was granted a furlough on September 10th, much improved. While lying in the field hospital in Cuba he was greatly exposed to wettings and bad climate.

Case VII.—Henry P. Darby, Company D, Thirteenth Infantry. On July 1st he was wounded by a Mauser bullet, which perforated the left arm and entered the left side of the thorax, fracturing the fourth rib in the axillary line. It penetrated both lungs and escaped from the right side of the thorax between the fourth and fifth ribs in the posterior axillary line. After being wounded he was subjected to considerable exposure before reaching the General Hospital at Siboney, Cuba. There, when seen about July 10th, his temperature was about 103.6° F. Respiration labored and very rapid, heart displaced well over to the right of the sternum, and there was absolute flatness over the entire left chest. Thoracentesis yielded fluid blood, only a small quantity of which could be removed. Later this became purulent and Estlander's operation was finally necessary for his recovery.

Case VIII.—James Scanlon, Troop K, Third Cavalry. Wounded on July 2d by a Mauser bullet, which entered the right side of the thorax over the third rib in the midclavicular line, passed downward and backward through lungs, diaphragm, liver, and abdominal cavity, pierced the right iliac bone, and emerged from the gluteal region. He had but little hæmoptysis. He lay in the Division Hospital for some time on the wet ground, and was exposed to the worst conditions of weather. On admission to the Relief he was in great pain over the right chest and the entire abdomen; had nausea and vomiting, dysentery, great dyspnea, and his temperature was hectic. The patient eventually died, August 19, 1898, of peritonitis and hæmoptothorax.

Case IX.—Mauser bullet entered the sixth interspace in the posterior axillary line and emerged in the corresponding interspace on the opposite side. There was some dyspnea and hæmoptysis, with slight effusion into the left pleura. There was no fever to indicate any purulent collection, and recovery followed without complications of any kind.

Case X.—Wounded by a Mauser bullet, which entered over the eighth rib in the posterior axillary line, and there was no wound of exit. The bullet was never recovered, and there were no resulting chest complications.

Case XI.—Otto Hornlein, Company C, Fourth Infantry. Wounded in left chest, but probably only superficially, without wounding the pleura. There was no hæmoptysis, and the wound over the chest healed rapidly.

Case XII.—John Taylor, Troop D, Tenth Cavalry. Was wounded at about two hundred yards' distance, the bullet entering just below the angle of the left scapula. It then lodged in the abdominal muscles about two inches from the umbilicus. He had hæmoptysis for several days. He made an uninterrupted recovery.

Case XIII.—Ernest Bender, Troop I, First Cavalry. Wounded through the left chest, but he made a complete and uneventful convalescence. No very detailed history of his injury was received.

Case XIV.—Edward O'Flaharty, Company C, Sixteenth Infantry. Wounded on July 2d by a .45-calibre ball from a bursting shrapnel, which entered near the angle of the right scapula and lodged beneath the skin in front, between the seventh and eighth ribs, after having traveled through the lung, diaphragm, and liver. The patient had hæmoptysis for several days, with some rise of temperature, which had, however, completely subsided in ten days from the time of the injury; no pleural or peritoneal effusion resulted, and he was discharged from the Long Island College Hospital cured.

Case XV.—William J. McIntyre, Company F, Seventeenth Infantry. Was wounded by a Mauser bullet at about five hundred yards' range, which entered just above the middle of the clavicle, exit just below the tip of the scapula. There was some hæmoptysis immediately after receiving the wound, but convalescence was entirely uncomplicated and complete.

Case XVI.—Wounded by a Mauser bullet, which entered the left side of the neck half an inch in front
of the median line, opposite the thyroid gland, and made its exit on the right side of the chest at the fifth rib opposite the posterior axillary line. This fractured the clavicle at the inner third and caused an arteriovenous aneurysm. No pulmonary symptom other than slight hemoptysis developed, and recovery was perfect.

Case XVII.—William A. Cooper, Troop A, Tenth Cavalry. A Mauser bullet entered the flesh over the chest an inch to the right of the left nipple and made its exit an inch below the costal margin on the right side in the mammary line. It is just possible that it did not wound the pleura at all, though at a very late date the history of hemoptysis was elicited from the patient. His chest injuries healed promptly and without any resulting complications, but an intercurrent dysentery confined him to his bed for some time.

The histories of seven other cases were secured whose wounds healed promptly without complications. These are so similar to the above-recorded cases that room is not taken to include them in this report.

From the cases here presented we are at once impressed with the fact that while the effect of the modern gunshot injuries to the chest is humane, we have a sufficient percentage of unfavorable results to greatly modify this claim. Out of twenty-four cases we have nine, or nearly thirty-seven per cent., in which hemothorax or empyema developed. There may be many more patients who promptly recovered, and certainly only a very few, if any, who had complications, but those who did, and whose histories we have before us, give us much important information. We can clearly infer that if they could have been treated under other conditions, as in time of peace, their results might have been less formidable. This is obviously impracticable in time of war, but offers valuable suggestions for the management of these cases at such time.

In the Santiago campaign the wounded had to be carried in ambulances, over roads that baffle description, in order to reach the hospitals at Siboney, and this was done some eight or ten days after the wounds were received. Moreover, while in the division hospitals on the San Juan River, they were but poorly sheltered, and were subjected to very severe weather, two conditions which would favor continued bleeding on the one hand and infection on the other. Illustrations of this we have in the first nine cases—the development of hemothorax, which in most instances was not discovered until twelve or fourteen days after the wounds were received, and it was more than likely that prior to this time it did not exist to any marked degree, but formed gradually because of the inability to maintain perfect quiet and rest in the treatment. In three of these (Cases I, II, and III) the blood in the pleura was absorbed without becoming infected, and in all the others (excepting Cases VI and VIII) the breaking down of the thorax to form pus was a late complication. Thoracentesis showed blood only as late as the twentieth day in Case IV; nineteenth day in Case V; tenth day in Case VII, and in Case II blood only when the patient arrived at the hospital at Fort Monroe. In each of these cases, however, operation was ultimately necessary for empyema. In all except Case VI the external wounds of entrance and exit healed promptly, and the patient had no symptoms which would indicate infection at the time of injury. Case VI might have been no exception to this had not the injured man been compelled to lie on the ground, exposed to wet and cold, shortly after being wounded. From these facts it seems evident that in the majority of these cases the cause of infection of this collection of blood in the pleura was not the bullet directly; the micro-organisms must have gained access to this most fertile soil from the wounded lung. In Case V, indeed, we find that the development of empyema after the nineteenth day was on the side opposite to the wound of entrance.

These facts point clearly to most important suggestions in the treatment of all chest injuries in time of war. They are always to be looked upon as most dangerous wounds, especially in the eyes of the soldier himself, so that they will be handled with especial care from the time of injury. And the utmost care must be persevered with in their treatment for several weeks, until all danger of further hemorrhage into the pleura is past.

The indications for treatment are twofold: First, to guard against infection at this time, when conditions are so favorable for that serious complication, and second, to check hemorrhage as soon as possible; for a collection of blood in the pleura or a hematocele in the lung is a most fertile ground for saprophytic invasion, and acts itself as a foreign irritant. The first is met by promptly cleansing and applying the first-aid sterile dressing, and using special precautions during convalescence to prevent exposure and infection that would lead to any general inflammatory condition of the lungs. We know that a bronchitis, pneumonia, or any inflammatory condition of the lungs presents a favorable soil for the ever-present micro-organisms and soon breeds them into their more virulent form, thus greatly favoring the eventual formation of empyema or lung abscess, especially where there has been bleeding. The second indication is met by making it thoroughly understood, especially among the soldiers themselves, that all chest wounds are serious, and that the patient must be kept absolutely quiet and passive, avoiding talking and active motions of all kinds, and transferred with the gentlest care, preferably on a litter, over rough ground. The surgeon should employ the usual methods of controlling internal hemorrhages, as keeping the injured side at rest by strapping and the use of opium, the administration of internal astringents, local use of cold, enforced use of bedpan, etc.

Undoubtedly, we have in chest injuries a condition which calls for the utmost care and painstaking, in order to prevent a fatal or a most serious and deforming result.
THE USE OF PAROTID-GLAND EXTRACT IN THE
TREATMENT OF OVARIAN DISEASE.*

By E. PIERRE MALLETT, M.D.

I was led to use this extract from reports made by Dr. Bell, of Edinburgh, in 1896, and later by Dr. J. B. Shoher, of Philadelphia. The theory which led Dr. Bell to experiment in this line of treatment was (in speaking of the use of thyroid extract in treatment of carcinoma of the uterus) that when local disease began in an individual the organ which it took possession of must have departed from a healthy condition prior to this, and that the weakened condition of the organ affected might have been influenced by a morbid or functionally altered state of an organ in close physiological relationship. The healthy action of the skin, the mucous membrane, and the adjacent connective tissue appears to be dependent upon some peculiar action of the thyroid gland, as shown by recent studies in myxedema and psoriasis. Therefore, why may not epithelioma of the cervix uteri, which arises in the epithelial layer of the mucous membrane, be due to the absence of some obscure catalytic influence of this gland? It has also been observed that disease of the thyroid gland is often accompanied by an excessive metrorrhagia, showing that the function of this gland exerts some potent influence upon the lining membrane of the uterine canal. Epithelioma does not attack a previously normal cervix uteri, but if there is present any lesion, such as laceration or hypertrophy due to long-standing endometritis or endometriosis, then this unhealthy state acts as a predisposing cause to the development, not only of epithelioma, but to affections of less virulent type. The close physiological sympathy existing between the mammae and the uterus suggested the use of mammary-gland extract in fibroid tumors of the uterus, while the physiological relation shown between the parotid gland and the ovaries led to the use of the parotid extract in ovarian disease. In the cases reported, the parotid-gland extract was for the most part used in conjunction with the usual routine treatment of ichthylol tampons in the vagina, but the rapid improvement, both symptomatically and anatomically, of those patients getting the parotid extract left no doubt whatever of the great value of this preparation in the class of cases in which it was used. While it is admitted that I am enthusiastic about this new preparation, I do not profess to have found the long-looked-for panacea for the frailties of the feminine flesh, but rather wish to call the attention of the profession to a comparatively new and as yet unrecognized agent in the treatment of these cases, whose place is as yet unassigned and its limitations not defined. I also wish to be clearly understood before citing cases that I consider myself to be, in a measure at least, familiar with—those hopeless conditions of pus in the pelvis which can only be treated by radical operation—and the glandular extracts are not advocated for such cases, but rather for that large and constantly increasing class of cases included under the broad term of salpingo-oophoritis, a term covering a multitude of clinical and pathological inaccuracies, or rather unproved assertions. The preparation used was that made by the Phospho-albumin Company, of Chicago—glandule parotidce in three-grain capsules. The substance, from results obtained, seems of uniform strength and produced absolutely no untoward symptoms in any case.

I report twenty cases in which the parotid-gland extract was used. In five cases the chief symptoms were severe dysmenorrhoea, and pains in the ovarian regions and back. The local conditions accompanying these symptoms were enlarged, tender, and prolapsed ovaries, varying in size, degree, and displacement. Upon the administration of this preparation, together with usual local treatment, the dysmenorrhoea was relieved and the enlarged and tender ovaries became apparently normal in a remarkably short period of time as compared with the usual local treatment alone.

Two cases seemed to show the action of the extract most clearly. In both cases the ovary at a previous operation had been carefully examined, found to be practically normal, and returned to the abdomen. The patients remained well for some months, one six and the other five, after which time they began to have pains again, and on examination the right ovary of each was felt to be enlarged and very tender. Both were treated in the usual way with tampons and douches without result until the parotid extract was given, when the ovaries in both instances became normal to the touch and the symptoms (pains) were relieved. The results in a number of cases of retroverted and adherent uteri with enlarged and tender prolapsed ovaries were equally gratifying. Upon the administration of the parotid extract the ovaries became less sensitive and smaller, and the exudate binding the uterus and appendages together seemed to soften, so that upon careful abdomen-pelvic massage the uterus could be raised, the appendages pushed up into place, and the symptoms relieved much more rapidly than in other similar cases.

To summarize, I would not attempt any physiological explanation of the action of the parotid gland on the ovarian structure, but would simply state some of its effects as I have observed them.

I. It has seemed to relieve the pains of dysmenorrhoea in all cases, without regard to the supposed cause or pathological condition present, to a greater extent than any of the numerous so-called uterine sedatives, all of which I have used.

II. It relieves those dull, aching pains referred to

* Read before the Society of the Alumni of the City (Charity) Hospital, April 12, 1899.
the back and ovarian regions, usually designated by those familiar though vague and unsatisfying terms, reflex pains, ovarian neuralgia, etc.

III. Menstruation, when deranged, seems to become more regular as to periodicity, less in amount, and shorter in duration.

IV. During its exhibition, pelvic exudate seems to soften and become absorbed more rapidly under abdomino-pelvic massage.

V. The general health, strength, and spirits seem to improve during its use, and those dull headaches which constitute such a persistent and annoying symptom in these cases are almost invariably relieved, and in some disappear entirely.

VI. The only counter-indication that I have thus far met with to its use has been in cases of the artificial climacteric (following double salpingo-oophorectomies), in which cases the flashes of heat and cold were made distinctly more frequent and severe.

It results from these facts that greater importance must be placed on increased accuracy in diagnosis. The time has passed when successful removal of the appendages is wondered at. Among men who have the true interest both of their patients and the profession at heart, it is rather incumbent upon the operator to prove that it was necessary to remove them at all; and any therapeutic agent seeming, as this one does, to combat the tendency to pathological changes in the widespread and all-important conditions I have been considering assumes professional and quite as much national importance. In the words of Dr. Bell, "An immense field for observation seems to be opening out, and will surely repay any amount of time expended upon elucidating these recondite physiological problems."

EXTRADURAL SPINAL MENINGEAL HEMORRHAGE.

WITH REPORT OF A CASE.

By S. D. HOPKINS, M.D.

ADJUNCT PROFESSOR OF NEUROLOGY IN GROSS MEDICAL COLLEGE AND NEUROLOGIST TO THE ARAFAH COUNTY HOSPITAL AND ST. ANTHONY'S HOSPITAL.

The patient, J. M., was admitted to St. Joseph's Hospital June 16, 1898.

His family history is negative.

Previous History.—Had the usual diseases of childhood, after which he enjoyed good health until his present illness. Denies syphilis and alcoholism.

Present illness began June 13, 1898. While he was shoveling coal from a car on to a truck he experienced a peculiar sensation throughout the body; the patient is unable to give any fuller account of this sensation, only that it was peculiar and was not painful. After loading the wagon he crawled from the car to the truck and drove to the scales.

During this time the "peculiar sensations" still persisted, and on arriving at his destination he was unable to descend to the ground on account of paralysis of the lower limbs. The time which elapsed from the beginning of this peculiar sensation to reaching his destination was about twenty minutes. On being assisted from the wagon he immediately complained of sharp, exacerbating pains in the lower portion of the back, extending around to the abdomen and down the thighs.

He was seen at this time by Dr. H. B. Curtis, who found him in the following condition: The patient was suffering severe pain in the lower portion of the trunk and down the thighs. Motor power of legs was entirely lost, also sensation in lower portion of the trunk and legs, excepting a small spot on the inner side of the left leg, where a prick of a pin was perceived. Pulse was normal; temperature normal. Pain was relieved by large doses of morphia. In the course of twenty-four hours the motor power of the left leg gradually returned, and by the end of the second day was fairly good. Sensation gradually returned. Reflexes at first were abolished. Had incontinence of urine.

I saw the patient on the third day of his illness. He was suffering pain in the same location, and of the same character as described above. The motor power of the left leg was good in every direction, but he was unable to make the slightest movement with the right. Sensation was present throughout the body. Knee-jerks: Right, absent; left, increased. Ankle clonus absent. Deep reflexes of forearm: Right, about normal; left, the same. Masseter reflex absent. Plantar reflexes: Right, slight; left, absent. Abdominal reflex was not taken. There was no ataxia nor paralysis in the arms. Facial muscles were normal. All the special senses were normal. At no time in the history of the case was the intelligence impaired. No evidence of atheroma of the blood-vessels. At the time of the examination the patient complained of a giddy sensation, and had incontinence of urine and faces. The following day the patient was in the same general condition, excepting that nausea was added. During the evening he made a sudden movement, suffered severe pain in the back, and in a few minutes had a general convulsion, in which he died.

From the foregoing symptoms the diagnosis of spinal meningeal hemorrhage was made, and was confirmed at the autopsy, held about eighteen hours after death.

Nothing abnormal was found until the spinal canal was opened. On removing the spinous processes, the canal external to the dura was found to be filled with liquid blood and a few small clots. The latter were found in the lumbar region. The membranes of the cord were slightly congested. The cord was normal.

In arriving at a diagnosis in the case one can readily exclude disease of the brain by the non-involvement of the cranial nerves and the character of the paralysis, along with the concomitant symptoms of spinal-cord lesions. The sudden onset of the symptoms would exclude all spinal lesions in the adult, excepting the vascular and those produced by sudden compression of the cord by displacement of the bone.

In hemorrhage into the spinal cord the paralytic symptoms, as a rule, come on immediately, and are persistent, along with the localized pain occurring at the
point of rupture, which is not so severe, and at times may be entirely absent; although in some cases, where the haemorrhage is large and breaks through the substance of the cord into the membranes, there will be added the irritating symptoms of meningal haemorrhage.

Extradural spinal meningeal haemorrhage is not a common occurrence in the adult, except following some injury, such as blows or falls; while in the newborn it is comparatively a common occurrence, probably due to rupture of a cerebral meningeal vessel during birth and the blood descending to the spinal membranes, although Schaffer reports one hundred autopsies of newborn infants in which ten had blood extravasated into the vertebral canal without the meninges of the brain being involved.

In the case under discussion none of the common pathologic factors were found to account for the hemorrhage, and after studying the case the only cause that I was able to ascertain was severe muscular strain or overexertion, which is the rarest of all the pathologic factors.

William Bain* reported a case similar to the one under discussion occurring in a girl, eighteen years of age, who was troubled with constipation. On December 21, 1894, in the evening, she took a cathartic for her bowel trouble; rested well, got up about 6 A.M., and in half an hour her bowels moved; returned to work and complained of numb and tingling sensation all over the body. When the physician was called the patient was in the following condition: Complained of difficulty in breathing, pain in the back of the neck, loss of motion and numbness in the upper and lower extremities. Mental condition good. Temperature, 98° F.; pulse, 52; could not move the left arm nor the right leg, but she could move the left leg with an effort, and the fingers of the right hand slowly. Knee-jerks absent. Sensation distinctly lessened. Patient went into collapse and died.

Post-mortem showed a comparatively small clot of blood at the third cervical vertebra between the dura and bone, the longer portion being on the right side. Severe muscular strain was the only cause found in the case.

The most common location for spinal meningeal haemorrhage to occur is in the cervical region. The location of the pain, paraplegia coming on suddenly, with no involvement of the upper extremities or respiration, in the case which I have reported, would lead one to the opinion that the haemorrhage occurred primarily in the lumbar region of the spinal canal, as was demonstrated to be the case at the post-mortem.

The convulsion in the case I have just reported must have been due to great irritation of the spinal membranes, or the medulla, or both, by the large quantity of blood. It has been demonstrated that if we irritate the membranes of the spinal cord or brain, convulsive movements will ensue. The sudden termination was probably due to paralysis of the cardiac and respiratory centres by pressure.

THE Puerperal STATE
AND Puerperal HÆMORRHAGE.

BY WALKER BOURNE GOSSETT, M.D.,
INSTRUCTOR IN OBSTETRICS IN LOUISVILLE MEDICAL COLLEGE.

I shall, no doubt, be criticised for the stand I have taken on the derivation of the terms puerperal state and puerperal haemorrhage and their classification, especially since it is contrary to all the authors, but "so mote it be."

I have been very kindly assisted in my derivation from the Latin by my friend Professor William T. St. Clair, professor of Latin in the medical department of Kentucky University and the Louisville Male High School.

Puerperal hemorrhage is not only the hemorrhage occurring during the delivery of the child (full term) and after, but is any hemorrhage from the uterus that is due to conception and occurring before, during, or after the expulsion of the contents of the pregnant uterus, whether it occurs at the first, second, third, or ninth month of gestation. When a hemorrhage occurs before the end of the sixth month it is generally called hemorrhage of a threatened abortion, or an abortion, and between this time and full term, a hemorrhage due to a premature labor, and is only called a puerperal hemorrhage after the beginning of the pains for the expulsion of the full-term child, and by most authors not until after the completion of the second stage of labor, and what they believe is the beginning of the puerperal state. This is, in my mind, erroneous. Take the derivation of the word puerperal: all the authorities give the same derivation from the Latin, to bring forth a child, of or pertaining to childbirth.

Hirst, in his text-book of obstetrics, says: "The puerperal state, or the puerperium, comprises the time from the termination of labor until the uterus has regained its natural size. This period in the normal case is six weeks. And in explanation of this belief, the word 'puerperium' comes from puer, a child, and pario, to bear, and denoted in the original Latin the childbed period, the lying-in period; so it is an appropriate term to designate this one of the periods in obstetrics—pregnancy, labor, the puerperium, and lactation."

I consider Hirst's classification of the four periods in obstetrics incorrect, and think they should be thus classified as three periods—which I shall try to prove later on:

* British Medical Journal, August 21, 1897, p. 455.
1. Pregnancy.
2. The puerperal state (labor and convalescence).
3. Lactation.

Grandin and Jarman say: “The puerperal state begins with the expulsion of the placenta, which event terminates the third stage of labor.”

The puerperal state does not begin between any of the three stages of labor, but at the very beginning of labor, which I shall prove.

King’s Manual of Obstetrics: “The condition of being in ‘childbed,’ whether during or shortly after parturition, is known as the ‘puerperal state’ (from puer, a child; and parere, to bring forth).”

He is certainly correct in that; but King goes on and says, “The term, however, is generally restricted, nowadays, to a period of four or five weeks immediately following the completion of labor.”

The following is taken from the Century Dictionary: “Puerperal (from Latin puerpera, bringing forth, a parturient woman; puer, a child; parere, bring forth, bear), of or pertaining to childbirth.

Parturient, bringing forth, or about to bring forth, young.

Parturition (L., parturitus, pp. of parturire, desire to bring forth, to be in labor), the act of bringing forth, or being delivered of young.”

From the Latin-English Dictionary, abridged from the larger work of White and Riddle, by John T. White, D. D. Oxon., vicar of St. Martin Ludgate, London: “Puer-per-us, a, wn, adj. (from puer-par-us; fr. puer; par-io).”

Bringing forth children, lying-in, in childbed: uxor, Sen.; verba, formulae that promote delivery, Ov. As subst. 1. puerpera, a, f. (se. mulier), a woman in labor, or in childbed, a lying-in woman; Hor. 2. A woman who has recently brought forth; Pl. puerperium, ii, n. (puerper-a) (a thing pertaining to a puerpera; hence), 1. Prop.: childbirth, childbed, a lying-in, confinement, delivery; Plant.; Tac. ii. Meton.: A newborn child; an infant; children; Tac.”

Puerperal is an English adjectival form of the Latin adjective puerperalis, meaning “pertaining to, caused by, or following childbirth.”

In medical language it is always febris puerperalis, meaning “puerperal fever”; in non-medical language it is written febris or ta ex puerperio (fever arising from childbirth), or febris que puerperium sequitur (fever which follows childbirth). Puerperalis is derived from puerpera, which, along with puerperium, is a compound of two Latin words, viz.: puer, child, and the verb partio—parere—peperi—partum, to bring forth (by birth).

Puerperium is a neuter noun of the second declension, meaning “the condition of a woman who is laboring, or (and) who has been delivered”; and also denotes the six weeks’ period after delivery. To what period or periods is the term puerperal to be applied? From the beginning of labor pains, and including the first, second, and third stages of labor to six weeks following. Since partio means “to give birth to,” or “bringing forth,” the root of this verb has been compounded with puer, and has been applied (by nearly all authors) to a specified time following the expulsion of the child. But why limit the application in this manner? By what right shall we arbitrarily affirm that the adjectival term puerperal, “pertaining to childbirth,” is to be limited or restricted in its application to this particular period? By considering the Latin word in its true meaning in the genius of its own language, rather than by an interpretation from a standpoint in our language, we shall secure a right conception of its proper signification.

Let us deal first with the true meaning as conveyed in the Latinity of the word, showing clearly and indisputably its original signification; and, secondly, with the corresponding technical terms derived from these and recorded in medical language, and sanctioned by metonymy, figure of speech, etc.

Take, for instance, partus, a familiar form of the verb partio. Partus has, in a strictly original sense, two distinct meanings equally important. The first meaning—the one in common use—is “bringing forth” or “birth,” from which is derived, by figure of speech, the technical term “parturition.” Second, it means a “begging,” and the word is much used in this very sense in classical Latin; from this meaning are derived, by metonymy, such terms as young, offspring, as well as fetus or embryo. Bearing in mind these two meanings, “begetting” and “birth,” we turn to another Latin word, satus, to which is usually given the secondary meaning “offspring” or “child,” while literally it means “one having been sown (as seed),” from the verb sero, meaning to sow seed. The connection between the sown seed and the child is obvious.

Again, the Latin word gentus, meaning in general terms “offspring” or “child,” really means in a strict sense “one begotten,” from the verb gigno, to beget. In each instance cited the Latin word for child has the original meaning to beget or to sow seed.

The logical conclusion based upon the correct meanings of words under consideration is that, when a woman conceives, she is with child. These Latin words—partio, as well as the others—do not necessarily imply a fully developed nine-months’ child. On the other hand, the rational conclusion is that they refer to, designate, and may be applied to any stage or period of a woman’s pregnancy, whether it be one, two, three, or nine months from the time of the “begetting (conception).”

Hence, I believe that the Latin word in its true meaning supports the theory that the term “puerperal” is not to be restricted to a particular period of a woman’s pregnancy; certainly no more to the producing or bringing-forth state of the full-term child than to the bringing forth of the one-, two-, or three-months fetus.
I think I have proved from the Latin that the puerperal state should include from the beginning of labor to about six weeks after the completion of the labor—the time of recovery.

Now, in brief, the word puerperal comes from puer, a child, and parere, to bring forth—of or pertaining to childbirth. Then the word means to bring forth a child—of or pertaining to childbirth. When is a woman with child? As soon as she conceives she is certainly with child. To be with child certainly means to be pregnant.

Then the following is my belief: That the puerperal state begins as soon as the labor pains begin for the emptying of the pregnant uterus, and lasts until the uterus is emptied and the woman recovers from that pregnancy, whether it be at first, second, third, or ninth month of pregnancy.

Hemorrhage beginning at the second, third month, etc., when it is due to the state of pregnancy, should be known as a puerperal hemorrhage of the second or third month. A point might be made that if there is a hemorrhage and the child (whether at full term or at any month) is not expelled and hemorrhage is stopped, this would not be in the puerperium; it is because the hemorrhage is due to the conception and the pains and hemorrhage had begun, but by treatment they were stopped. The same as in puerperal convulsion that is due to pregnancy—it is called a puerperal convulsion at whatever month it occurs, but generally puerperal convulsions occur in the latter months of pregnancy, and more often during the labor—in the first stage; but if convulsions occur at the first, second, third months, etc., and you thought the convulsions due to the presence of the child, or embryo, or fetus in utero, would you not call them puerperal convulsions, even if by treatment they were stopped? Also, in puerperal mania or insanity, is not the word puerperal used, even if mania or insanity occurs early in the pregnancy? So why draw the line at puerperal hemorrhage if convulsions, mania, and insanity are classified as puerperal when they occur early in the pregnancy or during the labor?

Classification of Puerperal Hemorrhage.—1. Ante-partum hemorrhage: (a) Accidental hemorrhage, or a normally situated placenta (subdivided into concealed hemorrhage and free hemorrhage) and (b) unavoidable hemorrhage, from an abnormally situated placenta—placenta previa. 2. Post-partum hemorrhage. Ante-partum hemorrhage is a hemorrhage occurring before the end of the second stage of labor. Post-partum hemorrhage is a hemorrhage occurring after the end of the second stage of labor, and within a month or six weeks. If occurring a month or six weeks after the completion of the labor, it should then be called a uterine hemorrhage. Accidental hemorrhage is a hemorrhage that is caused by an accident of any kind when a woman is in a state of pregnancy.

Accidental hemorrhage is divided into a concealed and free hemorrhage.

In a concealed hemorrhage the blood is retained in utero. The hemorrhage may be into the membranes or directly into the sac. The retained blood may bring on contractions, then a free hemorrhage. If not free, then generally there is relaxation of the uterus. The patient may bleed to death without any external flow of blood.

Unavoidable hemorrhage, due to an abnormally situated placenta—placenta previa. Post-partum hemorrhage, a very dangerous form and more frequent than any other, occurs after the second stage of labor, before or after the expulsion of the placenta.

The blood comes from the open mouths of the uterine blood-vessels, from which the placenta has, wholly or in part, been separated. If care is taken, the patient need not have hemorrhage very often. In a natural labor the hemorrhage is prevented by contraction of the fibres of the uterus and retraction of the mouths of the blood-vessels. Most cases of hemorrhage occur while the placenta is in utero, between the end of the second stage of labor and the expulsion of the placenta. In most cases the blood escapes, but it may be retained in the uterus. The hemorrhage is generally profuse, and the patient may bleed to death in a short time. The blood comes from large blood-vessels, both arteries and veins, the veins having no valves.

THE ETIOLOGY OF YELLOW FEVER.

ABSTRACT OF THE REPORT OF THE COMMISSION OF MEDICAL OFFICERS, MARINE-HOSPITAL SERVICE, DETAILED BY AUTHORITY OF THE PRESIDENT TO INVESTIGATE THE CAUSE OF YELLOW FEVER.*

The report embodies the work of the commission in fairly testing the claim of Professor Sanarelli, of Bologna, Italy, that the Bacillus icteroides is the cause of yellow fever, and the conclusion is drawn that this famous scientist has isolated the true cause of the terrible scourge.

This conclusion is based upon a careful bacteriological study, in the well-equipped laboratory of the Marine-Hospital Service in Havana, Cuba, of twenty-two cases of disease thought to be yellow fever by the native physicians in attendance.

Of these cases all were seen during the progress of

* Under date of November 8, 1897. Passed Assistant Surgeon (now Surgeon) Eugene Wadlin and Passed Assistant Surgeon H. D. Geddings were detailed by authority of the Secretary of the Treasury and the President as a commission to investigate in Havana the nature of yellow fever. Their full report, dated July 10, 1899, has been received, and is printed as a separate publication.
the disease, and in fourteen of them the commission concurred in the diagnosis.

Each case was the subject of careful bacteriologic study before and, if practicable, after death. This consisted in the abstraction of blood in sterile bulb tubes from the ear tip under careful asepsis. This blood was then diluted in the bulbs with meat-peptone bouillon, and after an incubation of twenty-four hours the growth was transplanted to fresh tubes of bouillon, from which, after twenty-four hours, Petri plates were made in series. From these the organisms present in the blood were isolated in pure cultures and studied. After isolation each organism was subjected to cultural examination on all media, by means of which those meeting the demands of Sanarelli for the organism he discovered were readily selected and their pathogenicity for animals established.

Of the fourteen cases diagnosed as yellow fever, the commission isolated the organism of Sanarelli, the *Bacillus icteroides*, from thirteen, and in the case in which this organism escaped the observation of the commission it was isolated by an independent observer, for whom tube cultures had been taken at an autopsy conducted by the commission.

Thus the even percentage of isolations has been obtained in these fourteen cases, all of which presented prominent symptoms of the disease. In the cases not thus diagnosticated the organism of Sanarelli was not obtained.

From the living blood in twelve of the fourteen cases, abstracted not earlier than the third day of the disease, the organism was isolated, and in the two others it was obtained post mortem.

The commission, having preserved a number of cultures made at the isolation hospital in the city of New Orleans, from cases seen during the epidemic of 1897, also isolated therefrom the *Bacillus icteroides* in the proportion of 83.33 per cent. of the cases examined, the cultures having been made at autopsy.

Thus the identity of the *Bacillus icteroides* of our Southern States with that found in Cuba, and that sent the commission by Professor Sanarelli, which was obtained in South America, was established.

As a check to these examinations the commission made use of a number of cases suffering from diseases other than yellow fever, from which the blood, extracted in the same manner and treated in the same way, failed to yield any organism at all comparable to Sanarelli’s. These diseases were representative of those usual to the city of Havana, and were seen during the same period of time in which the cases of yellow fever were under observation.

Also there were thirty-one dead bodies examined, bodies dead from known and unknown diseases, many of them in the city morgue, the most of them in the Spanish military hospitals. In each instance careful section was made and the blood from the heart, from the liver, the spleen, and the kidneys, urine, and faces planted directly into bouillon or upon agar-agar slant tubes, from which cultures series of plates were made.

All bodies thus examined, at times many hours after death, yielded colonies of various organisms, save one, and this case at the time of autopsy was diagnosticated pathologically as yellow fever, and the body was sterile.

In none of these cases of comparative autopsic examination was the *Bacillus icteroides* found; neither in the blood, the urine, nor the faces. Therefore, the commission assumes that the organism of Sanarelli is found only in bodies sick with or dead from the disease of yellow fever, at the same time conceding that in many of the sick the blood does not yield the germ, and that in the dead it may prove absent only under certain conditions.

Coincident with the foregoing observations the commission carried on the study of the natural history of the organism as to its mode of entering the body; its colonization therein; its toxic possibilities, and its distribution in the organs post mortem.

Numerous and interesting experiments were made with animals, the commission finding all the animals at its command, such as mice, rats, dogs, cats, guinea-pigs, rabbits, and monkeys, quite susceptible to the artificial infections produced by inoculating them under the skin, intraperitoneally, and endovascularly. At the same time it became convinced that the same or very similar results were obtainable by the use of other organisms of different kinds. It found, as had been stated by Sternberg, that similar clinical and anatomical results could be found after the artificial administration of the *Bacillus X*, as well as that of Havergal, and of the *Bacillus coli communis*, all of which proved, artificially exhibited, very pathogenic to all animals, and autopsies upon these revealed similar conditions in the organs. Moreover, the toxins elaborated *in vitro* by the above-named organisms, *X*, Havergal, *coli communis*, and icteroides, were precipitated, purified, and tested comparatively upon animals, with the result that the commission decided that the mode of death from these toxins, when injected into animals, was the same in kind, and that the toxins differed only in intensity, and that of these the *Bacillus icteroides* produced the most potent.

From these facts the commission, early in their work, became convinced that the claim of Professor Sanarelli, of having discovered the germ of yellow fever, was not established by any evidence presented in his published works, and that it was not tenable so long as it could be maintained that the bacillus of Havergal and the bacillus *X* of Sternberg produced the same pathological conditions when artificially inoculated, and the commission recognized the validity of this claim in view of the facts given above, although it had for a long time recognized both of these organisms as belonging to the colon group.
At this stage of its work the solution of the problem seemed very remote, but before turning to some other and unknown cause of this disease it was determined to place experimental animals under natural conditions of infection, since it was recognized that all preceding experimental work was so artificial that it was impossible for the commission to judge of the pathogenic, or rather specific, merits of the three prominent organisms.

From this animal experimentation the commission proves the natural specificity of the organism of Sanarelli; the absolute innocuousness of the Bacillus coli communis, of the Bacillus X, and of the bacillus of Havelburg, to even the most susceptible of animals; and a marked degree of similarity in the reaction of these animals (mice) to the acute infectious organisms, such as Bacillus typhosus and Bacillus cholerae suis, when exhibited to them naturally. The Sanarelli organism is thus eliminated from the colon group and associated with the acute infectious organisms.

The commission recognized that Sanarelli's claim was only one of pathogenicity and not of specificity; that until such demonstration of specificity there could be no valid claim for his organism. This validity the commission believes to have established in the conclusion that the Bacillus icteroides is "naturally infectious to animals, the degree varying with the species; that in some rodents local infection is most quickly followed by blood infection; and while in rabbits and dogs there is no evidence of this subsequent invasion of the blood, monkeys react to the infection the same as man."

The commission has determined "that the infection takes place by way of the respiratory tract," and that the primary colonization in the lungs is responsible for the first evidences of absorptive intoxication, such as fever, pains, etc., characteristic of the disease. Also that this primary colonization in the lungs and its poison symptoms may constitute the entire attack of the disease in many instances, an attack so light, so ephemeral, that even the most expert diagnosticians may not distinguish it from other ephemera, or from poorly marked attacks of allied diseases, such, for instance, as dengue.

Moreover, the conclusion has been reached that what is known in the literature of yellow fever as the "reactionary fever," the "secondary infection" (from microorganisms normal to the body), and the "secondary paroxysm," is due to the passage of the infecting germ, the Bacillus icteroides, from its primary colony in the lungs into the general circulation, thus producing the "secondary paroxysm" so familiar clinically in all marked cases, unless they are of the siderant type.

This "secondary paroxysm" is, then, a septicemic one, and it depends not upon the Bacillus coli communis, or Bacillus proteus, or upon the micrococci, but upon the further colonization of the specific organism in the blood, thus bearing out Fuget's observation that the "decline" of the fever, the true "secondary paroxysm," is as specific as the "rise," or the primary attack.

The commission recognizes the coincident invasion of the blood by the organisms of the respiratory tract, among which are found colon and proteus, as of possible, it may be frequent, occurrence; or these may invade from the alimentary canal "during the last hours of life," when the mucosa becomes impaired from stasis, and this invasion becomes possible. Such mixed septicemia must be of most severe type and frequently fatal.

The commission, therefore, differs entirely with Professor Sanarelli in his theory that the disease of yellow fever is primarily a septicemia. Indeed, it can scarcely be a matter of surprise that Sanarelli formulated this opinion, seeing that he always produced, with (as he thought) unimportant exceptions, artificial infections by internal inoculations, which perforce must have produced septicemia. Those cases not open to such explanation, which he observed in man, he explained in a still more unsatisfactory way; in fact, by the assumption that the germ elected to hide away in the spleen in small numbers during the whole course of the disease, only to suddenly come forth and produce a septicemia at its termination.

The commission, therefore, concludes that the theory of Sanarelli in this regard is not sustained by the facts of these cases, and offers the foregoing solution of probably the most widely and generally observed characteristic of yellow fever, the "secondary paroxysm" characterized by a septicemia.

The theory formulated and expressed by Dr. Sternberg, United States Army, that the "germinal principle" in yellow fever was to be looked for in the alimentary tract, an opinion evidently dependent upon the well-known influence of the disease upon the organs adjacent and contributive to this tract and portions of the tract itself, such as the duodenum, has been found untenable by the commission, since there is no record of any one ever having isolated the specific germ from this canal save in the case of its presence there through some capillary hemorrhage into its lumen.

The influence of the various disinfecting agents upon the Bacillus icteroides has been studied by the commission with an eye to the practical advantages to be derived from a better acquaintance with the organism, and it is found that the organism is readily influenced by the mechanical and chemical agents in ordinary use. Cold, however, is not a factor in this process, for the organism resists the most extensive refrigeration, and no reliance can be placed on this mode of disinfection. On the other hand, the organism is very susceptible to dehydration, and can not withstand artificial drying for more than ten to twelve days, and it is very probable that its susceptibility to frost is due to the lessened humidity of the atmosphere at such seasons rather than to the degree of cold experienced. Sunlight is very fatal to this organism, and no doubt is
more so if the organism has lost its vitality through evaporation of its fluids, as in a frosty atmosphere.

The resemblance between the Bacillus icteroides, in its behavior on certain media, and the bacillus of hog cholera has been brought to the attention of the commission, and it has deemed the observation that there is a possible similarity in the pathogenicity of the two organisms in the domestic hog of great importance, although its experience in the observation of the cultural similarities leads to the conclusion that they are culturally distinct; while the infection of the domestic hog, in its experience, is impossible by the method pursued of feeding the Bacillus icteroides to them.

However, the question being too much importance to be determined without full data, the commission placed under treatment a number of domestic hogs, in an environment free from suspicion of the possibility of any contamination with the Bacillus cholerae suis, with a view to deciding the question of the reaction of these animals to the Bacillus icteroides, administered to them in pure cultures in their food. These experiments were conducted at the United States Quarantine Station at Delaware Breakwater, and therefrom it is deduced, first, that the domestic pig is incapable of infection from the Bacillus icteroides when introduced through the intestinal or digestive tract, and second, that the Bacillus icteroides, when fed to pigs, will not produce any of the lesions or intestinal symptoms of hog cholera.

**Conclusions of the Commission.**

1. That the micro-organism discovered by Professor Giuseppe Sanarelli, of the University of Bologna, Italy, and by him named "Bacillus icteroides," is the cause of yellow fever.

2. That yellow fever is naturally infectious to certain animals, the degree varying with the species; that in some rodents local infection is very quickly followed by blood infection; and that, while in dogs and rabbits there is no evidence of this subsequent invasion of the blood, monkeys react to the infection the same as man.

3. That infection takes place by way of the respiratory tract, the primary colonization in this tract giving rise to the earlier manifestations of the disease.

4. That in many cases of the disease, probably a majority, the primary infection, or colonization in the lungs, is followed by a "secondary infection," or a secondary colonization of this organism in the blood of the patient. This secondary infection may be complicated by the concomitant passage of other organisms into the blood, or this complication may arise during the last hours of life.

5. That there is no evidence to support the theory advanced by Professor Sanarelli that this disease is primarily a septicaemia, inasmuch as cases do occur in which the Bacillus icteroides can not be found in the blood or organs in which it might be deposited therefrom.

6. That there exists no causal relationship between the Bacillus X of Sternberg and this highly infectious disease, and that the Bacillus X is frequently found in the intestinal contents of normal animals and of man, as well as in the urine and the bronchial secretion.

7. That, as far as our commission is aware, the Bacillus icteroides has never been found in any body other than one infected with yellow fever; and that whatever may be the cultural similarities between this and other micro-organisms, it is characterized by a specificity which is distinctive.

8. That the Bacillus icteroides is very susceptible to the influences injurious to bacterial life; and that its ready control by the processes of disinfection, chemical and mechanical, is assured.

9. That the Bacillus icteroides produces in vitro, as well as in vitrA, a toxine of the most marked potency; and that, from our present knowledge, there exists a reasonable possibility of the ultimate production of an antiserum more potent than that of Professor Sanarelli.

**REPORT OF SIX CASES OF PNEUMONIA TREATED WITH ANTIPNEUMONIC SERUM.***

**BY ANTONIO FANONI, M.D.**

In the number of the New York Medical Journal for May 7, 1898, I published a report of a case of pneumonia which I had treated successfully with the antipneumonic serum. As a result, I have received a number of inquiries from physicians all over the country about the technique of injecting the serum, and concerning the quantity which should be used in the most severe cases. Since then I have had under my observation five additional cases of the disease.

Before giving the histories of these patients I will briefly describe the technique of injecting the serum.

The anti-pneumonic serum was discovered by Professor Pane, of the Royal University of Naples, and was first introduced to the medical world in a paper which Dr. Pane read before the Royal Academy of Medicine of Naples in 1897.† The serum was first tried in Professor De Renzi's medical clinic in Naples, and gave very promising results.

The serum is prepared in two strengths—No. 1 is mild, and No. 2 is more concentrated and stronger. The first is used in the milder cases and early in the disease, while the second is reserved for the more severe types of pneumonia. In the most malignant cases the

dose should be doubled or even tripled. The writer was surprised at the results which he obtained in some of his own cases, for they were in several instances of a most desperate character.

The best site for the injection is along the posterior axillary line. The injection is given twice a day, say at 8 or 9 A.M., and again between 8 and 10 P.M. The usual dose is ten cubic centimetres at each injection. The syringe used may be a large hypodermic, and it is well to sterilize the instrument before each injection by washing in a four-per-cent. solution of carbolic acid. The skin must also be disinfected by means of a solution of bichloride of mercury (HgCl₂, 1, H₂O 1,000, and HCl 10) applied on a piece of absorbent cotton. It is best to make the first injection in the posterior axillary line, between the eleventh and twelfth ribs, so as to leave a sufficient space for later injections. The puncture is covered by a thin layer of cotton soaked in the bichloride solution. The patient is then placed upon the side where the injection was made, and remains in that posture for about ten minutes, so as not to displace the cotton.

By these means the occurrence of suppuration is avoided. I may state, however, that in some cases I did not use any antiseptic measures on the skin either before or after injection, and yet there was no sign of sepsis.

The injections should be used regularly, both in the morning and in the evening, while the fever exceeds 104° F. If the fever subsides and there are no asthenic symptoms, we may suspend the injections, and thus save the patient the expense of serum treatment. But if the temperature rises again, we have to resume the injections. When the fever remains under 104° F., and there are other severe general symptoms, it will be necessary to continue the use of the serum until the patient’s condition begins to improve.

Where the serum is used, all other medication must be omitted, and only the hygienic measures to be described later should be employed. The daily diet should comprise a litre and a half or two litres of milk and one or two cups of broth, with the yolks of an egg. In addition, the patient may be given some alcohol and water. De Renzi gives thirty grammes of alcohol in five hundred of water on the first day, thirty-five on the second, and so on, until sixty or seventy grammes in twenty-four hours are reached. This last dose is never exceeded.

Personally, I have never given this stimulant unless the necessity for such a measure was very apparent.

In asserting that this serum is a safe and reliable remedy in the treatment of pneumonia, the writer was by no means actuated by patriotism, but by a conviction born of his own experience.

The best proof of its efficiency is the fact that it has been used with success when death was expected within twenty-four hours. But if the pre-agonistic stage is reached—I. e., when septicemia had set in—there is no hope for the patient even in serum therapy.

The success which has attended the use of this remedy in Italy makes it possible to state that the De Renzi Pane’s serum is a positive specific in the treatment of pneumonia. Among those who have tried the remedy with good results are the following directors of medical clinics connected with Italian universities: Massalongo, of Verona; Maragliano, of Genoa; Cantieri, of Siena; Belfanti, of Milan; Bozzolo, and many others.

The serum has also been used in lobar pneumonia, in idiopathic meningitis, in epidemic cerebro-spinal meningitis, in pleurisy, pericarditis, peritonitis, etc., as in all these diseases the pneumococcus has been found at one time or another by various investigators.

Since 1898 I have used it in six cases of pneumonia in my private practice, and have obtained a remarkable series of successes.

There is a great deal of satisfaction in the knowledge that we now have a remedy which attacks the cause of the disease, and that it is no longer necessary to witness the progress of pneumonia with the feeling that we are powerless and can do nothing except to try to stimulate the heart, to give expectorants, and to attempt to reduce the temperature by some antipyretic measure.

The mortality of pneumonia is certainly considerable, and I firmly believe that the serum would have been a blessing to many a family from whom this disease has taken away a dear one. I would therefore urge my fellow practitioners not to give up a case of pneumonia until they have tried this means of treatment. In fact, I hope there may come a time when it will be regarded as the principal, if not the sole, remedy in this disease.

Case I.—A. T., aged thirty-seven years; the patient had been ill with influenza for four days, and was suddenly seized with a chill, fever, a severe pain in the left side of the chest, and difficult respiration. I saw the patient four days later, and found the physical signs of a lobar pneumonia in the inferior lobe of the left lung. The temperature was 104° F., the respiration 46, the pulse 116. There was dry cough with rust-colored sputum. At four o’clock on the same day (February 27, 1898) I injected ten cubic centimetres of serum No. 1, which had been sent to me from Naples two days previously. At 9 P.M. the temperature was 103° F., the respiration 40, and the pulse 112. The subjective symptoms were somewhat less marked.

February 28th, at 10 A.M., the temperature was 102.5°, the respiration 36, the pulse 106. Second injection of ten cubic centimetres of serum No. 1. At 9 P.M. the temperature was 103° F., the respiration 41, and the pulse 114. Third injection March 1st. At 11 A.M. the temperature was 102° F., the respiration 31, pulse 100. Fourth injection. At 9.30 P.M. the temperature was 101°, the respiration 31, the pulse 90.

* IX. Congresso di medicina interna, tenuto a Torino, Ottobre, 1898. Estratto dalla Nuova rivista clinico-terapeutica, fasc. 11, 1898.
Fifth injection. General condition good and physical signs showed beginning of resolution.

March 2d.—The patient felt fairly well, and rested better than the preceding nights. The temperature was 102° F., the respiration 34, the pulse 92. Sixth injection. At 9 p.m. on the same day the temperature was 101.5° F., the respiration 31, the pulse 86. Seventh injection. Auscultation showed the presence of sub-crepitant rales.

3d.—At 10 a.m. the patient's breathing was normal. She passed a quiet night, and had scarcely any cough. Temperature, 98° F.; pulse, 76; breathing, 31.

The temperature was subnormal for the next three or four days; the general condition showed a quick and progressive resolution of the pneumonic process.

Case II.—A. C., aged thirty-seven years; was seized at night with acute lacertinating pains in the left side of the chest. A physician who was called declared that he had an acute lobar (croupous) pneumonia. Another physician was next consulted and told the family that the patient had a very severe pneumonia, and that he had better be taken to the hospital, as he could not receive the proper amount of care at home.

On the fourth day I was called to his bedside. I found a lobar pneumonia involving the inferior lobe of the left lung. The temperature was 104° F., the pulse 115, the breathing 44. A dry hacking cough, with scanty rust-colored sputum. There was pronounced dyspnea. I injected ten cubic centimetres of the serum. The patient was restless during the night; the cough became more violent, with efforts at vomiting. On the following morning the temperature was 103.5° F., the pulse 110, the respiration 42. The tongue was dry. Second injection.

On the next day the patient reported that he had rested well that night. Temperature, 100.5° F.; pulse, 103; respiration, 38. The patient felt a great deal better, and there was a noticeable improvement in the pneumonic process. The physical signs showed beginning of resolution. Third injection. In the evening the fever was 101.5°, the pulse 103, respiration 40. The patient rested well the following night.

On the next morning at 10 o'clock his temperature was 98° F., the pulse 96, the respiration 36. The physical examination showed the presence of redux crepitus.

On the following day the general condition was fair. The pulse was still small and rapid, but it was restored to normal by means of stimulants. Six days later the patient was perfectly well.

Case III.—G. R., forty-two years old, laborer; was suddenly seized with a severe chill, with fever and acute pain in the right side below the angle of the scapula. I was called on the fourth day after the chill. The patient was very much prostrated; he had delirium and dyspnea. At 4.30 p.m. the temperature was 102.5° F., the pulse 98, the respiration 48. He had a dry cough, without expectoration, and a dry tongue. On physical examination there were found dullness at the inferior right lobe and very fine pleuritic crepitus. I made the diagnosis pleuro-pneumonia. At 6 p.m. I saw the patient again. The temperature was 103.2°, the pulse 100, the breathing 50. I made the first injection with serum No. 1. At ten o'clock on the same day the patient's condition was the same. On the following day, at 9 a.m., the patient said that he was very much prostrated; he had passed a very bad night, suffering from delirium and intense dyspnea. He had had three diarrheal movements of the bowels during the night. Temperature, 102° F.; pulse, 96; breathing, 60. Auscultation revealed cracking rales in a limited area. He had cough, with scanty, rusty, viscid expectoration streaked with blood.

At ten o'clock the patient was worse; the tongue dry and rough. Temperature, 103.5° F.; pulse, 98; breathing, 50. I injected ten cubic centimetres of serum No. 2.

At nine o'clock on the next day the temperature was 103.5° F., pulse still 98, breathing 62. The patient reported that he had had during the night a severe pain above the nipple on the right side. I found that the pneumonic process was extending to the superior lobe. This certainly accounted for the rising temperature and the aggravation of the general symptoms. I again injected ten cubic centimetres of serum No. 2.

At eight o'clock in the evening the temperature was 103.5°; pulse, 102; respiration, 58.

The condition of the patient was so serious that the family where he was boarding proposed sending him to the hospital, as they did not like to see him die in their house. I objected to this, as I had not entirely abandoned hope, and injected another dose of serum. At 9 a.m. the next day the patient was somewhat improved; he had passed a better night than the preceding one. Temperature, 103° F.; pulse, 102; respiration, 58.

Although the patient was in the sixth day of his disease, and the danger was increasing, he did not seem to lose any ground. I injected twenty cubic centimetres of serum (ten cubic centimetres of serum No. 2 and ten cubic centimetres of No. 1). While all the serum which I had used thus far had been prepared six months before, the serum No. 1 used in the last injection was dated only four months previously. Serum loses all its efficacy five months after its preparation, and this was the cause of the failure of the first injections in this case. Owing to this, I had lost some very valuable time.

At three o'clock the temperature was 103.8° F.; pulse, 112; breathing, 60.

At nine o'clock p.m. the temperature was 104° F.; pulse, 112; breathing, 62. I again injected twenty cubic centimetres of serum (ten cubic centimetres of No. 2, six months old, and ten of No. 1, four months old).

At nine o'clock the next morning the patient's condition was not worse. The night had been fair; temperature, 103.5°; pulse, 122; breathing, 60. I injected twenty cubic centimetres of serum as on the preceding day. At 1 p.m. the temperature was 104°; pulse, 126; breathing, 60. At nine o'clock the temperature was 103.5°; pulse, 136; breathing, 64. I injected twenty cubic centimetres of serum. I noticed some rales in the middle lobe of the right lung. The patient was feebler, and I ordered some wine, besides the alcohol that I had already been using for the last few days. The tongue and the throat were so dry that he spoke with difficulty.

At 9 a.m. the next day the temperature fell to 102° F.; pulse, 124; breathing, 54. The patient had passed a quiet night. Rales were heard over the entire affected side. There was little cough with scanty expectoration. The general condition was much improved.

At 9 p.m. there were evidences of resolution. Temperature, 101.5° F.; pulse, 132; intermittent; breath-
ing, 46. I prescribed some strychnine and injected some caffeine.

On the following day, at 11 o’clock A. M., the general condition was very good. Temperature, 100° F.; pulse, 98; breathing, 36. On the next day, at noon, the temperature was normal; pulse, 84; breathing, 28. The convalescence was somewhat prolonged.

This case was a characteristic one, as it demonstrated, as I have said, the inefficacy of the serum six months after its preparation. That insufficient serum did not prevent the extension of the disease, while the small quantity of the serum No. 1, four months old, saved the patient from a probable death. On account of the gravity of the case, on the sixth day of the disease, I sought to have injected forty or fifty cubic centimetres of efficient serum, but I only gave the usual dose, believing that it would be sufficient. This case, and the information given me later by the discoverers, shows that the serum positively loses its efficiency after five months. The makers have arranged to exchange packages of serum which are older than five months for fresh ones.

Case IV.—G. M., twenty years old, barber, had chills and pains in the right hypochondrium, high fever, slight dry cough, difficulty of breathing.

He had been ill for six days when I was called. Before I came he had been treated with the usual remedies by two other physicians. When I was requested to attend him his general condition was very much depressed. I noticed tympanitic dulness at the anterior right lobe; crepilant rales, bronchial breathing, dry cough, with scanty rusty expectoration; temperature, 103.5° F.; pulse, 115, feeble and compressible; breathing, 36. I injected some caffeine, and twenty cubic centimetres of serum No. 2. I prescribed some alcohol, according to the advice of Professor De Renzi and Professor Pane. In addition, I ordered milk and broth to be given during the night.

Next morning, at nine o’clock, I was surprised to find the patient in very fair condition. Pulse, 102; temperature had fallen to 99° F.; breathing, 30. The physical signs were also improved, with rales indicating resolution all over the affected area. The crisis had come. That night the temperature was 98° F.; pulse, 90; breathing, 28. General condition very good.

The temperature was subnormal for three days more, and the pulse gradually became normal. The convalescence was somewhat tedious and difficult, but some time after the man could resume his work.

Case V.—M. C., forty-five years old, married, had an attack of influenza, and a few days later she had acute pains on both sides of the chest, with chills and high fever. Dr. Joseph Tanner was called and found a bilateral lobar pneumonia. He told the family that the disease was of the most serious character and that the patient could hardly recover.

On the third day of the disease I was called to attend the patient. I confirmed Dr. Tanner’s diagnosis. The general condition was low; there was dullness at both inferior lobes of the lungs with diminished expansion. At one point some rales were heard; the temperature was 104°F.; pulse, 108; breathing, 36.

At 7 P.M. I saw the patient again. The general condition was unchanged. Temperature, 104.5° F.; pulse, 110; breathing, 36. I injected ten cubic centimetres of serum No. 2, four months old. At twelve o’clock on the next day the general condition was improved. The cough that was dry and troublesome is now accompanied by abundant expectoration of the characteristic color, and is less viscid than before; temperature, 101°; pulse, 105; breathing, 32.

I again injected ten cubic centimetres of the serum. At six o’clock the temperature was 102.5° F., the pulse 106, the breathing 33. Third injection. On the next day at eleven o’clock the temperature was 101.5°, pulse 120, breathing 38. The general condition is satisfactory. The patient had rested well that night. Fourth injection of serum No. 2. At four o’clock the temperature was 102° F., pulse 116, breathing 38. Fifth injection of serum. On the next day at twelve o’clock the temperature was 103° F., pulse 110, breathing 35. Sixth injection of serum. At 6.30 P.M. the temperature was 103.5° F., pulse 116, breathing 38.

On the next day, at twelve o’clock, the general condition was good. The night had been passed well. The temperature was 100.8° F., pulse 112, breathing 32. Seventh injection of serum. At 2 P.M., temperature, 102° F.; pulse, 114; breathing, 32. At 6 P.M. the temperature was the same; pulse, 116; breathing, 33.

On the following day, at twelve o’clock, the general condition was low; temperature normal, small and compressible intermittent pulse, rate 120. Rales indicating resolution at both pulmonary bases, with an abundant expectoration. The apex beat very feeble. On the next day the condition was unchanged. The patient could not recover strength, notwithstanding the tonics which she had been taking. Temperature normal; pulse, 130; breathing, 30.

The patient was in full convalescence, but her heart gave me some apprehension. I told the family to immediately summon me if anything happened. After six days, at seven o’clock in the morning, I received a telephone message to the effect that the patient had severe precordial pain and dyspnea. An hour later I found the patient dead.

Her death was certainly caused by pericarditis, or more probably endocarditis, which is frequently a sequel to pneumonia. The woman was very stout, and the family said that she had suffered from shortness of breath, when she was going upstairs, even before her illness.

Case VI.—P. P., laborer, married, forty-eight years old, was suddenly seized in the night with fever and severe chills. In the morning he felt a stabbing pain in the left breast, which extended to the back. Two physicians were called in, and only one of them recognized the pneumonia. He applied dry cups and prescribed an expectorant.

I visited the patient on the third day. At eleven o’clock the physical examination revealed a diminished expansion, exaggeration of the pulmonary voice, with the typical crepitant rales, and dull tympany on percussion. Temperature, 103.5° F.; pulse, 100; breathing, 30. I informed the family that the only specific remedy was the serum, and that all other remedies were to be suspended.

Dr. W. T. Wright, who desired to see a case treated with the serum, accompanied me. At six o’clock he ex-
amined the patient and made the same diagnosis of lobar pneumonia. The temperature had risen to 104.5° F.; pulse, 102; breathing, 31. I made an injection of ten cubic centimetres of serum No. 2, prepared on March 1st. There was delirium and severe prostration.

On the next day, at 9 a.m., the patient’s wife informed me that he had been resting quietly during the preceding night for the first time since he became ill. There was a dry, hacking cough, with more abundant and less rusty expectoration. During the physical examination he got an attack of epistaxis, which stopped after a short time. Temperature, 104.5° F.; pulse, 102; breathing, 32. I injected ten cubic centimetres of serum.

At four o’clock the temperature was the same; pulse, 100; breathing, 32. At 5.30 p.m. the temperature had fallen to 102.8° F.; pulse, 98; breathing, 30. The patient felt better and drank with pleasure two litres of milk. In presence of this improvement the family regained hope. The general condition of the patient was very satisfactory. The auscultation revealed râles over the left lobe, and the pulmonary process, which threatened to extend, remained stationary.

I injected twenty cubic centimetres of serum No. 2. On the next day, at nine o’clock, the patient stated that he had passed a good night. The general condition was unaltered. Temperature, 103° F.; pulse, 105; breathing, 36. I injected ten cubic centimetres of serum. At five o’clock the general condition was so much improved that the patient said he was well, and asked for something to eat. Temperature, 102.5° F.; pulse, 95; breathing, 29.

At 8.30 p.m., temperature, 102.2° F.; pulse, 94; breathing, 28. The patient had a good appetite, and two yolks of eggs were given him.

I made the sixth injection of serum. On the next day the patient stated that he had slept well throughout the night. General condition very good. Temperature, 100° F.; pulse, 80; breathing, 26. Expectoration nearly white. I did not inject any more serum, as the pneumatic process was undergoing resolution.

At eleven o’clock Dr. Wright and Dr. Tanner examined the patient, whom they had not seen since the third day of the disease, when the first injection was made. The doctors were surprised at the splendid results of the serum.

At 5 p.m., temperature, 100° F.; pulse, 78; breathing, 26.

At 8 p.m., temperature, 99° F.; pulse, 78; breathing, 26.

On the next day the temperature was normal; all other symptoms improved. General state very good. The convalescence in this case was very short, and a few days later the patient could resume his work.

The quantity of serum used in these cases was from a minimum of twenty cubic centimetres to a maximum of one hundred and twenty cubic centimetres.

In some of them only the serum No. 1 was used, in others only the No. 2, while in still others both strengths were given.

The resolution in these cases was as follows: First case, eighth day, by lysis; second case, sixth day, by lysis; third case, tenth day, by lysis; fourth case, seventh day, by crisis; fifth case, seventh day, by lysis; sixth case, sixth day, by lysis.

In making a report of these cases I have simply de-
and drawn down well into view, exposing its base; estimate the amount of tissue that should be left after excision is done, so that the cut edges can afterward be sutured accurately without tension. Apply a broad-ligament forceps to the base of the pile, the direction of the blades corresponding to the long axis of the bowel, draw the pile out well, and force the forceps down on the wall of the rectum so as to include as much of the base as possible. Now close the forceps and lock it tightly. Cut off the pile, leaving only enough of the tissues on the surface of the forceps so that the open mouths of vessels can be located and separately ligated, and the cut edges be accurately stitched with continuous sutures of medium-sized catgut. Remove all other piles in a similar manner; finally take off the forceps in the order in which they were applied. Under such circumstances the forceps are temporary hemostatics, levers, and tractors, and thus an addition to the immediate excision method. These uses of the forceps save time, enable the operator to perform his work quickly, with few manipulations, and without the aid of assistants. Thus the surgeon overcomes the slight inconveniences of the immediate excision operation — i. e., the necessity of having (1) to introduce a broad Sims speculum into the rectum in order (2) to locate, clamp, and ligate the bleeding vessels in the rectum, and (3) to pick up with forceps the cut edges so that they can be sutured.

Broad-ligament forceps have heretofore been used by some surgeons in hemorrhoidal operations.

I have used them in my last six cases (since December, 1898) as here described and with perfect satisfaction. I had previously used forceps as temporary hemostatics, levers, and tractors, in the enucleation method of ovariotomy, salpingectomy, etc., without ligation, clamp, or cautery, when the enucleation of the ovary or tube, etc., was somewhat difficult. Under such circumstances the forceps are an addition to the enucleation method.

326 Kearny Street.

Therapeutical Notes.

Tang-kin in Amenorrhoea and Dysmenorrhoea.—Hirth (Münchener medicinsche Wochenschrift, June 6th; Medical and Surgical Review of Reviews, July) says that the root of tang-kin, also known as kan-kin, schan-ki, and wön-wu (man-mo), has been used with good results by the Chinese for centuries in case of abnormal menstruation, especially amenorrhoea. The writer obtained a large supply in Chungking, in western China, in May, 1893, and brought it to Europe. It was examined pharmacologically by Heinz, of Munich, who found the extract non-poisonous, and not an abortifacient. Müller has given the drug an extended trial in cases of amenorrhoea and dysmenorrhoea, with favorable results. The writer believes that in this drug a valuable remedy will be found for the disturbances of menstruation. Extractum radicis tang-kin has now been placed on the market under the name of "enemol" (cumarol?).

Applications for Pruritus.—The Progrès médical for July 15th credits the following formula to R. Bonnier:

1. B. Gelatin .................................. 150 parts;
   Purified gelatin (grioléine) ........ 100 "
   Gum arabic .................................. 5 "
   Glycerol .................................. 100 "
   Boiled water, 1 each ....................... 300 "
   Zinc oxide .................................. 100 "
   Phenosal ................................. 2 "

2. M. Apply warm.

   Anhydrous lanolin, 1 each ............... 50 parts;
   Yellow wax .................................. 30 "
   Ichthyol .................................. 30 "
   Powdered iris .................................. 30 "
   Solution of rubber (solvent not specified) .......... 200 "

3. M. Incorporate the ichthyol with the lanolin with the aid of heat.

A Cinchona Jelly.—The Journal des praticiens for July 15th attributes this formula to Dr. Brissemore:

R. Caffeine .................................. 6 parts;
   Extract of cinchona ......................... 25 "
   Citric acid .................................. 4 "
   Tincture of vanilla .......................... 1 part;
   Tincture of lemon peel ...................... 4 parts;
   Rum .................................. 80 "
   Syrup .................................. 300 "
   Gelatin .................................. 30 "
   Glycerin .................................. 80 "
   Water .................................. 180 "

M. The dose is not stated, and the details of preparing the jelly are not given. The dose, however, is easily calculated, and any pharmacist will know how to make the jelly.

For Sensitive Dentine.—Dr. Bogue (Dental Brief; Southern Dental Journal, July) dips a pledge of cotton into carbolic acid, and then into powdered cocaine, and places it in the cavity. This, he says, will obtund the sensibility enough to use granulated chloride of zinc with little or no pain. In ninety seconds the insensibility of the cavity is complete.

A Cough Mixture.—Dr. L. M. Taylor (Merck's Archives, August) has used the following prescription with most satisfactory general results:

R. Chloral hydrate ......................... 64 grains;
   Ammonium carbonate ..................... 32 "
   Fluid extract of ipecacua 1 fluid drachm;
   Spirits of nitrous ether
   (Squibb) ............................... 2 fluid drachms;
   Syrup of tar. .............................. 1 fluid ounce;
   Syrup of wild cherry, ...................... 1 fluid ounce;
   Camphorated tincture of opium, ...........

Shake well and take a teaspoonful when the cough is troublesome.
THE AMERICAN DENTIST OF THE PRESENT DAY.

The art of dentistry is well known to have had its real origin in the United States. But it is not as a skilled and ingenious workman alone, or even chiefly, that the American dentist is to be regarded; he occupies a place second to nobody else's as a scientific investigator. If he takes up his abode in some European city—and he often does—it is not merely for the ingenuity displayed in the appliances he takes with him from his native land that he is distinguished; he soon makes it understood that he is practising for the love of his art, and that he is at the same time seeking by unsurpassed methods of scientific study to advance odontological science. Whoever of the medical profession may be unaware of this would lose nothing by attending a few meetings of the New York Odontological Society; indeed, he would probably pick up information that he might find of advantage in his own work. We mention that particular society simply because it is one of which we have knowledge founded on observation, and not because we imagine there are not other dental societies in the country that might serve as equally noteworthy examples of the progressive character of the dentist's work and the high position of odontology among the medical sciences; indeed, our present reflections have been prompted by a paper presented before the Section in Stomatology (a term, by the way, which we do not approve of) of the American Medical Association at the recent Columbus meeting, by Dr. Frederick B. Noyes, of Chicago, and published in the Journal of the American Medical Association for August 5th.

Dr. Noyes's paper was the outcome of a most painstaking histological study of the periodontal membrane, one fraught with exceptional technical difficulties, as the author explains. It is illustrated with fine half-tone reproductions of photomicrographs and a diagram of Dr. G. V. Black's. Unfortunately, the cuts are not numbered, though they are referred to by number in the text. Such an occurrence will occasionally mar the publication of an important article; the rush attending the preparation of a large weekly journal is such a tax on the editorial staff that nobody can justly be blamed for it, and certainly we should be the last to cast a stone at our excellent contemporary for a blemish which, after all, is probably to be imputed to the author's omission, impossible to repair if noticed at the last moment, and apt not to be noticed at all till the paper comes out. Like things have occurred in our own pages, and we do not expect to escape them so long as human faculties are finite.

Dr. Noyes's article is of value, not only by reason of the observations recorded in it, but also for the suggestions the author offers as to solving the problems that still confront the histologist with reference to certain epithelial structures found in the periodontal membrane, and for his criticism of argument that ought to be founded on histology; but has come with profusion from men who admit they have not made a histological study of the structures concerning the diseases of which they discourse. In other words, it is as an incentive to further work on the part of his fellow dentists that Dr. Noyes's paper is sure to prove of great value, for they are far too devoted to the advancement of odontology not to heed what he says. Admirable as their everyday work is, as recently exemplified in perfecting dental anaesthesia and in the use of porcelain fillings, it is subordinate to their intelligent and unremitting pursuit of the science that underlies their art. The American dentist of the present day is most assuredly in the advance guard of scientific progress.

DERANGEMENT OF THE RESPIRATORY TYPE IN CHOREA.

The plausible, and sometimes the barely possible, is too often put forward by medical writers as if it were indisputable. In other words, there is too much jumping to conclusions, too great a tendency to erect a crude bit of theorizing into a demonstration. A most commendable instance to the contrary is to be found in an article by Pignatti-Morano, published some months ago in the Clinica medica italiana. The author's conservatism is recognized by Finder, whose abstract of the article appears in the Deutsche Medicin-Zeitung for June 29th; he does not set the case down as one of "true respiratory chorea," says Finder, but as one of change of the respiratory type in a choreic.

Pignatti-Morano's observation is as follows: A boy, nine years old, was admitted into a hospital with chorea which had come on suddenly a few weeks before. His breathing attracted notice at once; to superficial observation it was decidedly accelerated, ranging from 90 to 130 a minute and more, but sphygmographic examination showed readily that there was no heightened rapid-
ity in the succession of normal respiratory movements, only a splitting up of each movement into two or three parts. Each normal movement of respiration was composed of two or three lesser movements, and so gave the impression of an accelerated respiratory type. Nothing further was noticeable about the organs of respiration. The phenomenon described disappeared during sleep. By an effort of will the boy could make a few normal respiratory movements, but they lasted only for some seconds. Neither rest nor exercise, remaining indoors nor going out into the open air, warmth nor cold had any influence on the breathing. The physician's approach or that of a stranger intensified the respiratory abnormity, and so also did the horizontal posture. The patient was much improved by the usual treatment for chorea.

The author questions whether the respiratory phenomenon observed in this case is to be looked upon as expressive of a subordination of the respiratory movements to the chorea or of a special primary affection of the respiratory centre, exaggerating its excitability and so giving rise to an alteration of the physiological type of respiration.

FORMALDEHYDE AS A POISON.

"The virtue of formalin has been its positive antiseptic and supposed non-toxic and non-irritant properties. It is being extensively used, not alone by physicians, but by the laity, and especially the farming community, as well. The ravages of the potato scab fungus, which has been so destructive to the tubers, have caused investigations at the agricultural experimental stations, with the result that bulletins were issued recommending the use of formalin as a safe and most reliable germicide." So says Dr. Charles Bock, resident physician to the Indiana School for Feebleminded Youth, after relating a case of fatal poisoning with formalin, in the Fort Wayne Medical Journal-Magazine for July.

On the farm connected with the school, a man was treating seed potatoes with the four-per-cent. solution of formaldehyde. During this man's temporary absence, one of the inmates, a "low-grade imbecile," twenty-six years old, strong and healthy, drank from an ounce to three ounces of the solution. He immediately complained of pain in the stomach and began to vomit. The vomited matter was stained with blood. Large quantities of albumen water were given at once, and he had but little difficulty in swallowing it. Free vomiting was produced with a tenth of a grain of aponomorphine given subcutaneously. At the end of two hours the man seemed but little the worse for his rash act, although he was somewhat weak and complained of slight pain in the stomach. The administration of albuminous drinks was continued and he seemed to improve until the sixteenth hour, when his pulse began to flag. It continued to grow weak and rose to 92 in frequency, in spite of repeated large doses of strychnine given subcutaneously, together with one dose of nitroglycerin and several doses of sparteine by the mouth. At the twenty-ninth hour his respiration was 40, he was getting restless, and his heart was failing.

Seventeen ounces of normal saline solution were injected under the skin, and two hours later sixteen ounces were thrown into a vein, but he presently died. During the last hour of his life there was occasional slight cyanosis.

At the post-mortem examination the upper and middle thirds of the esophagus showed slight signs of inflammation. The stomach contained four ounces of dark fluid free from formalin. Its walls were in some places more than an inch and a half thick and very edematous. The cardiac end was very red and highly inflamed. The remainder of the organ was necrotic, dark, and tough and cut like old leather. In the duodenum there was an inflamed area confined chiefly to the vitreally conniventes.

Evidently the public ought to be informed that formaldehyde preparations strong enough to be of value as antiseptics and germicides should be handled with caution and not left where children or imbeciles can get access to them.

THE DESCENDANTS OF AN ALCOHOLIC.

In our issue for August 12th, under the heading The Effects of Alcoholism on the Offspring, we mentioned the case of a French family showing such effects. Another example, on a gigantic scale, is afforded in a terrible catalogue of degeneracy which, according to Lyon médical for July 23d, citing Médecine moderne, has been uncovered by Professor Pellmann, of the University of Bonn, who has identified seven hundred and nine descendants of Ada Jurke, a confirmed alcoholic, who was born in 1740 and died in 1800. Seven of these descendants were convicted of murder, and seventy-six of various other crimes. One hundred and forty-four were professional beggars. Sixty-one lived on public charity, and one hundred and eighty-one were prostitutes. In surveillance, prosecutions, and maintenance in asylums or prisons, this family is said to have cost the German government the sum of six million francs.

SUDDEN DEATH IN CASES OF FATTY HEART.

Not in every case of fatty heart is there any great danger of sudden death, and when that termination does occur the mode of death is not always the same.

Bureau (Thèse de Paris, 1898; Centralblatt für innere
EDITORIAL ARTICLES.

310

Medcin, July 29, 1899) has studied the mechanism of sudden death in cases of fatty heart, and finds that it differs in the simple cases and in those complicated with atheroma of the coronary arteries, which latter are by far the more numerous. If there is atheroma, sudden death is apt to be caused by a rupture of the heart or occur during an attack of angina pectoris. In cases of simple fatty degeneration of the heart, however, death is not directly attributable to the heart, but is due to syncope, and the causes of that accident may be various. In young and otherwise healthy persons the fatal syncope may be brought about by some such cause as a forcible movement, a cold bath, an injury, or the like. In the anemic or cachectic with a fatty heart it may be induced by cerebral anemia occasioned by a sudden change from the horizontal to the upright posture. The patient should always be on his guard against syncope, and when it occurs it should be treated promptly.

INFLAMMATION OF THE VERMIFORM APPENDIX FOLLOWING CHILDBIRTH.

To mistake appendicular inflammation for disease of the uterus or its annexa is, of course, more apt to occur shortly after childbirth than at other times. It happened in a case related by Fieux at a recent meeting of the Bordeaux Society of Obstetrics and Gynecology (Gazette hebdomadaire de médecine et de chirurgie, July 13th), but fortunately the observation of tenderness at McBurney’s point led afterward to a correct diagnosis, and the appendix was removed. It showed lesions similar to those of typhoid fever; there were numerous glandular ulcerations.

“SYphilis” AND “PARASYPlilis.”

Tommasoli (Monatshefte für praktische Dermatologie, xxviii, 2; Centralblatt für Chirurgie, July 22d) reasons that the tertiary manifestations of syphilis must be the expressions of a self-intoxication with syphilis, or at least of a chronic infection which impresses peculiar changes upon the organs. The result, as he would call “syphilis,” is in contradistinction from ordinary syphilitic infection. And parasyphilitic symptoms, which may be caused by other poisonings, although not the chronic bacterial, he interprets as expressive of “parasyphilis.” We quite appreciate the Centralblatt’s writer’s comment: “Mit Worten lässt sich trefflich streiten.”

THE AGGLUTINATION OF TUBERCLE BACILLI.

The results of Widal’s test have led to experiments into the phenomena of agglutination in regard to other than typhoid bacilli. Courmont (Centralblatt für innere Medicin, No. 25; St. Louis Courier of Medicine, July) describes the method of obtaining agglutination phenomena in tubercle bacilli. Cultures eight to ten days old are best suited for this reaction; the serum of an animal not easily susceptible to tuberculosis, but which has been made tuberculous, is used as a test serum. Under the microscope tubercle bacilli show a peculiar tremulous motion; the author leaves it doubtful whether this is molecular in character or not. After the agglutination this motion disappears entirely. Macroscopically the agglutination reveals itself by a precipitation of the cloudy turbidity in the previously homogenous fluid. To elicit the reaction, three dilutions must be made—one in five, one in ten, and one in twenty. A positive reaction with the second dilution is decisive. The reaction was positive in ninety-six out of a hundred and six cases of human tuberculosis, and doubtful or negative in only ten, these latter being all cases of advanced phthisis with cavities. In common with the tuberculin test this reaction fails in the last stages of the disease. It is said, however, to be trustworthy in latent tuberculosis.

SUBCUTANEOUS INJECTIONS OF GELATIN IN THE TREATMENT OF ANEURYSM.

There has been some room for speculation as to the modus operandi of gelatin injections in the cure of aneurysm. LANCECREAU AND PAULASCO (Gazette des hôpitaux, 1898, Nos. 117 and 134; Centralblatt für innere Medicin, July 22, 1899), who have found the treatment decidedly more efficacious in secular than in fusiform aneurysms, suggest that the gelatin, being absorbed into the blood, enhances the coagulability of that fluid, and that two factors are at work to induce coagulation in the aneurysmal sac, namely, retardation of the flow of blood within the sac and the roughness of its interior.

A NEW DANGER FOR BICYCLISTS.

An extraordinary accident is reported to have happened recently at Muncie, Indiana. The pneumatic tire of the hind wheel of a bicycle exploded, and the explosion was so severe that, according to the New York Times for August 15th, the rider was thrown several feet into the air and dashed unconscious to the sidewalk. A physician, on reaching him, found him to be dying. The report of the explosion is said to have been audible for a great distance.

THE DOCTOR IN GENERAL LITERATURE AGAIN.

We have taken great pleasure in perusing a little book entitled EXTRA, by Dr. E. K. Goldsborough. It is almost wholly in negro dialect, and the humor is very enjoyable. Dr. Goldsborough dedicates it “to the mothers and daughters of the Sunny South,” and we can assure him and them that the sentiment of the dedication is shared by those who, nearly forty years ago, were arrayed in arms against the South.

THE BUBONIC PLAGUE IN EUROPE.

Now that the plague has reached Portugal and is rumored to have been carried to Spain also, our sanitary officers will undoubtedly take energetic measures to prevent its gaining a lodgment in our own country. While it is most likely to come here by way of some British port, if at all, it may come by some more direct route, and this possibility the Marine-Hospital Service will assuredly bear in mind.

X-RAY BURNS.

Apparently we are approaching the desirable condition of being able to use the Röntgen rays to the best advantage without risk of damage to the patient. The Electrical Review, in its issue for August 2d, intimates that the most improved apparatus, in the
hands of those highly skilled in its management, is alone free from danger, owing to the rapidity with which it acts. It refers to a Röntgen picture taken by Mr. E. W. Caldwell, of New York, by means of an exposure so brief as readily to have sufficed for a rapidly moving object.

A WARNING CONCERNING EXPLORATORY PUNCTURE OF THE CHEST IN CHILDREN.

A MOST uncomfortable experience is that of finding that one has provoked dangerous effects by the employment of means supposed to be harmless, and, unfortunately, it is not an uncommon one. The indiscriminate resort to tapping the chest to clear up a doubtful diagnosis may lead to such an experience, as is graphically set forth by Dr. Henry Koplik in the August number of Pediatrics. The warning should prove all the more effective because Dr. Koplik, in common with others, has before dwelt in his writings upon the harmlessness of the procedure. He now relates in brief the histories of four cases in which pulmonary hemorrhage followed the puncture. Fortunately, the result was not fatal in any of them, but the author points out that the conditions may not always be favorable to a prompt cessation of the bleeding, and adds that if they were not the child would probably die. It is rarely, he thinks, that more than one puncture at a sitting is justifiable. The needle, he says, should not be thrust in more than a third of an inch, it should be withdrawn rapidly (the whole procedure occupying not more than half a minute), its point should not be moved about in quest of fluid, and the puncture should be made cautiously on the left side of the chest, either in front or in the back, in the vicinity of the heart and great vessels or near the vertebral column. He states that he himself has never punctured in front over the apex of the lung and over the great vessels.

THE CANADIAN MEDICAL ASSOCIATION.

This year’s meeting, which is to be held in Toronto on the 30th and 31st of August and the 1st of September, Wednesday, Thursday, and Friday of next week, will probably be more largely attended than usual, on account of its occurring during an industrial exposition “illustrating the progress of the century.” The programme, which we print elsewhere in this issue, promises a profitable interchange of views and experience.

THE DEMONSTRATION OF THE TUBERCLE BACILLUS IN THE FECES.

Rosenblatt (Centralblatt für innere Medicin, 1899, No. 29; Settimana medica, July 29th), noting the difficulty of finding the tubercle bacillus in advanced cases of intestinal tuberculosis, owing to the fluidity of the stools with which the bacilli are mixed up, conceived the idea of administering tincture of opium until the stools become solid and formed. The micro-organisms are then sought for solely on the surface of the feces, where, it is said, they can be found without difficulty.

TUBERCULOUS DISEASE IN MAN AND BEAST.

At a recent sitting of a legislative committee to investigate animal diseases in the State of New York Dr. Edward Moore combated the accepted idea of the bovine origin of tuberculous disease in man. His paper is published in full in the Country Gentleman for August 10th. Whether Dr. Moore is right or wrong, he is convinced of the truth of his contention, as is shown by the following remarks, which occur in his paper: “I predict that you will find that where cattle tuberculosis is plenty, human tuberculosis is so rare as to bear no relation to it; that while you are in the thick of bovine tuberculosis, you are practically outside the consumptive belt. But again, I warn you not to accept my opinion. Go prove it right or wrong.”

ITEMS.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, cholera, and plague were reported to the surgeon-general during the week ending August 18, 1899:

Small-pox—United States.

Jacksonville, Fla. . . . . July 29-Aug. 12 . . . 9 cases.
Louisville, Ky. . . . . Aug. 3-10 . . . . 3 "
Everett, Mass. . . . . July 29-Aug. 5 . . . . 1 case.
New York, N. Y. . . . . Aug. 8-12 . . . . 1 "
Cleveland, Ohio . . . . Aug. 5-12 . . . . 4 cases.
Altona, Pa. . . . . Aug. 12 . . . . 2 "
Sokane, Wash. . . . . July 29-Aug. 5 . . . . 1 case.
Tacoma, Wash. . . . . July 29-Aug. 5 . . . . 1 "

Small-pox—Foreign.

Aden, Arabia . . . . May 1-30 . . . . 1 death.
Antwerp, Belgium . . . . July 22-29 . . . . 3 cases.
Rio de Janeiro, Brazil . . June 30–July 7 . . . . 39 "
Hongkong, China . . . June 24–July 15 . . . . 2 "
Athens, Greece . . . . July 22-29 . . . . 11 "
Bombay, India . . . . July 4-15 . . . . 15 "
Mexico, Mexico . . . . July 23-30 . . . . 7 "
Progresso, Mexico . . . . July 15-22 . . . . 2 "
Panama, Colombia . . . July 21-Aug. 1 . . . . 4 "
Moscow, Russia . . . . July 15-22 . . . . 7 "
Odessa, Russia . . . . July 22-29 . . . . 4 "
Warnaw, Russia . . . . July 8-29 . . . . 3 deaths.
Strait Settlements, Singapore . . June 24–July 1 . . . . 2 "
Smyrna, Turkey . . . . July 15-23 . . . . 1 death.

Yellow Fever—Foreign.

Bahia, Brazil . . . . July 16-21 . . . . 9 cases, 1 death.
Rio de Janeiro, Brazil . . June 30–July 7 . . . . 3 deaths.
Panama, Colombia . . . Aug. 1-8 . . . . 2 "
Havana, Cuba . . . . July 27-Aug. 3 . . . . 3 "
Santiago, Cuba . . . . July 22-29 . . . . 9 deaths.

Cholera.

Bombay, India . . . . July 4-18 . . . . 1 death.
Calcutta, India . . . . July 1-8 . . . . 4 deaths.

Plague.

Amoy, China . . . . July 8-15 . . . . 275 deaths.
Hongkong, China . . June 24–July 15 . . . 306 cases, 305 "
Alexandria, Egypt . . . . July 1-16 . . . . 7 "
Bombay, India . . . . July 4-18 . . . . 115 "
Calcutta, India . . . . July 1-8 . . . . 7 "

A Correction.—Dr. Chase P. Ambler calls our attention to an error in the abstract of his paper on Serum Therapy in Tuberculosis, which we published in our issue for August 12th, page 245. We inadvertently reversed the order of importance of the three factors essential to the treatment of tuberculosis. Dr. Ambler placed hygienic conditions first, climate second, and medication in the third place. We regret the error, which was purely one of oversight, and gladly comply with Dr. Ambler’s request to correct it.
Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 19, 1899:

The Baly Gold Medal.—We learn from Science for August 16th that the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London has awarded the Baly gold medal for distinguished services to the Royal College of Physicians of London.

The Malarial Mosquito.—According to the New York Times for August 23d, Major Ross, in charge of the Malaria Investigation Expedition, cabled from Sierra Leone on the 21st inst. to the Liverpool School of Tropical Medicine that the malarial mosquito had been found.

Change of Address.—Dr. T. H. Merrill, from Tacoma, Washington, to Brockton, Massachusetts.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 12 to August 19, 1899:

Agramonte, A., Acting Assistant Surgeon, United States Army, will return to Havana.

Bradley, Alfred E., Major and Surgeon, United States Volunteers, upon being relieved by Perley, Henry O., Major and Surgeon, United States Army, as commanding officer of the United States hospital ship Relief, at San Francisco, will proceed to join his proper station, Fort Yellowstone, Wyoming.

Hartuff, Albert, Lieutenant-Colonel and Deputy Surgeon-General, United States Army, is granted leave of absence for one month.

Duvall, Douglas F., First Lieutenant and Assistant Surgeon, United States Army, will proceed to Brooklyn and report to Arthur, William H., Major and Surgeon, United States Army, commanding the United States hospital ship Missouri, for duty.

MacDonald, Charles E., Acting Assistant Surgeon, United States Army, will proceed to Fort Yates, North Dakota, relieving Griswold, Edward T., Acting Assistant Surgeon, United States Army, who will proceed to Fort Meade, South Dakota, for duty.

Noble, Charles D., Acting Assistant Surgeon, United States Army, will accompany recruits ordered from Columbus Barracks, Ohio, to San Francisco, and return to his proper station.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Week ending August 19, 1899:

Atlee, L. W., Surgeon. Detached from the Bennington and ordered to the Solace.

Baldwin, L. B., Surgeon. Ordered to be examined by the naval retiring board at Washington, September 12th, and then home to await orders.

Bebee, D. G., Assistant Surgeon. Detached from the Monadnock and ordered to the Bennington.

Bogan, F. R., Assistant Surgeon. Detached from the Wabash and ordered to the Scorpion.

Furlong, F. M., Assistant Surgeon. Detached from the Solace and ordered to the Oregon.

Lippitt, T. M., Assistant Surgeon. Detached from the Solace and ordered to the Baltimore.

Thompson, J. C., Assistant Surgeon. Detached from the Baltimore and ordered to the Castine.

Wheeler, W. M., Assistant Surgeon. Detached from the Baltimore and ordered to the Solace.

Wilson, H. D., Passed Assistant Surgeon. Detached from the Castine and ordered to the Solace.

Promotions.

Births, Marriages, and Deaths.

Married.

Burger—Vandewater.—In Ocean Grove, New Jersey, on Tuesday, August 15th, the Rev. Edward Burger and Miss Emma Louise Vandewater, daughter of Dr. Albertus L. Vandewater, of Hackensack, New Jersey.

Foot—Beach.—In Gloversville, New York, on Tuesday, August 5th, Mr. George Lewis Foot and Miss Elizabeth Warren Beach, daughter of Dr. Eugene Beach.

Harbour—Hamblen.—In Vosburg, Mississippi, on Wednesday, August 16th, Dr. George L. Harbour and Miss Nellie Hamblen.

Died.

Dederick.—In St. Francisville, Louisiana, on Wednesday, August 16th, Dr. John William Dederick, in the eightieth year of his age.

Hartman.—In Westchester, Pennsylvania, on Wednesday, August 16th, Dr. William D. Hartman, in the eighty-fourth year of his age.

Shepard.—In New Orleans, on Tuesday, August 15th, Dr. Edward T. Shepard, in the fifty-sixth year of his age.

Thom.—In Baltimore, on Monday, August 21st, Dr. J. Pembroke Thom, in the seventy-first year of his age.

Letters to the Editor.

MEDICATION OF THE MIDDLE EAR.

PITTSBURGH, PA., August 14, 1899.

To the Editor of the New York Medical Journal:

Sir: It is with pleasure and profit I have read the article by M. A. Goldstein, M. D., in the New York Medical Journal of July 29th, entitled Modern Therapy of the Tympanic Cavity, for your humble serv-
ant has been working upon similar lines for some little time, only, instead of using a syringe with a piston, I have been introducing into the tympanic cavity the medicated compounds of petroleum by means of a fountain syringe having a glass reservoir and pure rubber tubing, in connection with the silver Eustachian catheter, all apparatus and preparations being sterilized. Placing my patient on the back, with head inclined in such a position as to give the most direct vertical flow of the fluid through the Eustachian tube, I allow the medicament to force itself slowly within, the receptacle being placed at the height of eight feet. After the withdrawal of the catheter, my patients, remaining on the back, have been asked to inflate the ear by the Val-salva method, thus forcing more of the fluid within the cavity. The fluid certainly enters the tympanic cavity, for my patients have not only felt it there and the sensation of its being against the tympanic membrane, but have expressed themselves as having experienced the slow issuing from the Eustachian tube into the nose and mouth of the preparation introduced for two and three days after. This treatment has measurably bettered the condition of the sclerotic tympanic membrane, modified and lessened the tinnitus, and improved the hearing somewhat in a progressive case of aural sclerosis of thirteen years’ standing.

As regards the introduction of fluids within the tympanic cavity by the hypodermic syringe with a long needle, this is a matter I had thought out before reading or knowing any one had done so, and expressed the wish that some one would do this, hesitating to be the first to do so. Also, I had practised the introduction of petroleum compounds with the fountain syringe into the middle-ear cavity, the ear so treated having the tympanic membrane unruptured, before I knew any one had tried so to do.

I wish some specialists located in some of our large cities, where there are supposed to be plenty of patients to try this treatment upon, would in the cases of sclerotic ears introduce through the drumhead a small quantity of warm normal salt solution, fill the external ear with the same, fill the nostril of the corresponding side with cotton, saturated also with the same salt solution, and apply the negative pole of the galvanic battery to the solution within the external ear, and the positive pole within the nose, employing a moderate current for at least half an hour. My experience with this method of procedure in cases of atrophic nasal catarrh and the excellent results obtained lead me to believe that good may be done, inasmuch as the sclerotic ear is in much the same condition (as I understand it). Patience and persistence are requisite.

Andrew T. Veezer, M. D.

FOR A HOLIDAY TRIP, REST, RECREATION.

Toronto, July 29, 1899.

To the Editor of the New York Medical Journal:

Sirs: It occurs to me that many of the overworked, holiday-needing readers of your valuable weekly, especially those practising in your city, would be glad to read a suggestion or two in respect to places of rest or of soul-stirring recreation, and the way to get to them.

There is one route, reaching across the continent, which I think, as a whole, is not very well known in New York and which for diversity of scenery, of methods of transit, of climatic variety agreeably limited, and for length of continuous trip can hardly be equaled on the continent, probably not excelled anywhere. From start to finish there are constant agreeable changes. One can, of course, take it as a whole or in part; from two hundred to three hundred miles, or especially five hundred, to over three thousand miles.

This route is by way of the Lehigh Valley Railroad to Niagara Falls; by the Grand Trunk or, if preferred, by boat across the lake to Toronto, and then to Muskoka by the Grand Trunk; by boat along the enchanting lakes of this region and on over the Georgian Bay and Lakes Huron and Superior, through the Sault Ste-Marie Canal, to Fort William. Thence the route is by the Canadian Pacific Railway through the picturesque, richly-stored mineral regions of northern Ontario, through the rolling, diversified, or more or less wooded prairies of Manitoba and the Northwest Territories, with their cool, ozonized, refreshing breezes to, and literally through, the mighty Rocky Mountain range, and the Selkirk Range, the Gold Range, and the Coast Range, to the Pacific.

The tourist can leave the boat at the Sault and, instead of going through northern Ontario and Manitou, go by rail through Michigan, Minnesota, and North Dakota, touching at Minneapolis and St. Paul, and join the main line of the Canadian Pacific before it dips into the grandeur of the Rockies. Or one may travel the entire route by rail, the Grand Trunk making close connection with the Pacific road near North Bay, on the south side of Lake Nipissing.

The first four hundred and fifty miles of this route is made an exceedingly pleasant trip by the Lehigh Valley management, especially if one rides on the “Black Diamond Express,” said to be the handomest train in the world, with its special observation car for passengers to view the panoramic scenery, its café, library, and well-filtered atmosphere. The rich agricultural valleys, with their countless fruit farms and orchards, of New Jersey; the highly picturesque mountain region—the Switzerland of America—the Wyoming Valley, and the Susquehanna River, of Pennsylvania; and the beautiful lake regions of New York are successively traversed, and the tourist reaches Buffalo and the Falls of Niagara, of which Anthony Trollope wrote: “I know of no one thing so beautiful, so glorious, and so powerful,” and “Of all the sights of this earth of ours . . . I am inclined to give the palm to Niagara Falls.”

From the Falls to Toronto, and on to Muskoka, the Grand Trunk cars, now not second to any others for the comfort of passengers, for speed, pure air, etc., pass through a rich agricultural country and curve along the shores of Lakes Ontario and Simcoe.

In boats, supplied with every comfort, over the three principal lakes of Muskoka, with their countless and beautiful islands, and over the great Georgian Bay (lake) and Lakes Huron and Superior, the trip is delightful to the eye and, especially on the larger lakes, most exhilarating to the whole organism.

From Fort William, on Thunder Bay, a great lake, the Canadian Pacific Railway furnishes the best possible means of transport. The facilities for the comfort of tourists can hardly be surpassed in any way—luxurious parlor, sleeping, and dining cars, with a pure atmosphere therein, and, in the Rockies, a special observation car.

And a few words here about the Rockies, along this road, will be of interest. They are entered between two almost vertical walls of dizzy height, forming a
gateway through which the Bow River from the moun-
tains pours out. Then, as Lady Macdonald has written it, "Very striking and magnificent grows the prospect as we penetrate into the mountains, each curve of the line bringing fresh vistas of endless peaks rolling away before and around us, all tinted rose, blush-pink, and silver, as the sun lights their snowy tips. Every turn becomes a fresh mystery, for some huge mountain seems to stand right across our way; yet a few minutes later we find the giant has been encircled and conquered, and soon lies far away in another direction." Grandeur and beauty crowd ceaselessly upon the attention as we proceed through gorge and over mountain, giving now a vast outlook, in a moment, an interior glimpse; the scenes changing with the suddenness almost of a kalei-
doscope.

With an "unlimited" ticket the tourist can, with great advantage, stop over at points of most interest—as, for example, at Mauch Chunk (Indian for Bear Mountain), and ascend, at an acclivity of forty degrees, Mount Pisgah, by the Switchback Railroad, which carries up twenty thousand human sightseers annually, and view the country at an elevation of fifteen hundred feet; again, at Geneva, and visit Seneca Lake, surrounded by an excellent road, eighty miles in length, highly tempting to bicyclists, and, at the lake's outlet, that remarkable, fascinating spot, Watkins Glen; and again, if a Waltonian, one can spend some time at one or more of the many trout lakes on the route. The beautiful, shaded, breezy city of Toronto is well worth a stop-over at, say at the time of the meeting here of the Canadian Medical Association—August 30 and 31 and September 1st; and one may rusticate pleasantly for a day or two in Muskoka if the weather be not damp. The strongly sulphured Banff hot springs, at the National Park on the Rockies, at an elevation of forty-five hundred feet, should be visited. Here in Devil's-head Lake are enormous trout, for which deep trolling affords fine sport, and wild sheep and mountain goats are common on the neighboring heights.

Of this delightful place, the secretary of the Ontario provincial board of health, Dr. Bryce, writes: "The climate is Alpine, and has an atmosphere of such ethereal clearness, freshness, and purity as at times to seem to almost transport the visitor into a supernatural region. There is a beautiful hotel, with every modern accommodation, convenient to the hot springs, in the midst of splendid scenery, open from May to October; and a mountain sanitarium under expert medical supervision. . . . The effects of the climate and springs here on rheumatic affections and diseases of nutrition have been for years favorably proved by hundreds of invalids." The springs are at different elevations on the eastern aspect of Sulphur Mountain, the highest being seven hundred feet above the Bow. All may be reached by good roads, commanding glorious landscape views. The more important ones have been improved by the government, and picturesque bathing houses erected, under the care of attendants. One spring forms a pool inside a dome-roofed cave; another, near by, forms an open basin of warm sulphurous water.

Primary Cancer of the Fallopian Tube—Daniel (Thèse de Lille, 1899; British Medical Journal, August 12th) has collected over thirty authentic cases of primary cancer of the Fallopian tube, and adds an extra one operated upon by Delassas, of Lille.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

BY ARTHUR N. TAYLOR, LL.D.

CIVIL MALPRACTICE, INCLUDING GENERAL LIABILITY OF PHYSICIAN TO PATIENT.

(Continued from page 275.)

Liability for Erroneous Conclusion in Examination.

A peculiar case of injury resulting from an erroneous conclusion of a physician is shown in a recent Massachusetts case.6 In this case the plaintiff, who was engaged to be married, had accidentally injured himself in such a way as to require the attention of a physician and the application of remedies to his private parts. The father of the plaintiff's fiancée, hearing that the plaintiff was afflicted with a venereal disease, took him to the defendant, a physician, for the purpose of learning his real condition. The physician examined the plaintiff and reported that he had gonorrhea, whereupon the plaintiff's fiancée broke the engagement, and the plaintiff brought suit against the physician for damages.

It will be observed that this case presents conditions differing from all others heretofore considered: a third party employs a physician to examine a man, the physician does so, and erroneously reports his condition. Is the physician beholden to the man examined for damages resulting from his incorrect diagnosis? Here there is no contractual relation existing between the physician and the man whom he examines, for he is in the em-
ploy of the third party. We have seen, however, that a physician who undertakes the treatment of a case gratuitously is under equal obligation to the patient as though the patient paid him for the treatment. So, also, is the physician bound to possess the same qualification and exercise the same skill in the treatment of a patient where he is paid for such treatment by a third party. Therefore in this case the fact that the physician was employed by a third party to conduct the examination can not be urged as a bar to the plaintiff's right to recover. But does the mere fact that the physician made an erroneous report of the plaintiff's condition entitle the plaintiff to recover from him for damages resulting therefrom? Here, again, we find the old familiar rule that the physician is not liable for his incorrect report if he has the ordinary skill and learning of a physician, and exercised ordinary diligence and care in their application to the case; otherwise he is liable. Nor does the fact that the purpose of the examination was information and not medical treatment have any material effect.

Examining without Consent.—An English case arising from an examination similar to the one related above, in which the party examined submitted only with reluctance, and afterward sued the physician for assault in making the examination under coercion, presents quite a different question for consideration. In this case a housemaid was accused by her mistress of being in the family way; the girl denied the accusation, but the mis-
tress sent her to her room and sent for a physician to

---

* Harjott vs. Plimpton, 166 Mass., 585.
† Dubois vs. Decker, 120 N. Y., 325.
examine her. The physician on arriving went to the
girl's room and told her he had come to examine her;
the girl objected, and said she did not like to be exami-
ned; the doctor explained that he was a professional
man and told her how to prepare herself for examination;
she did as directed, and submitted to the examina-
tion, crying all the time. The doctor found that the
mistress's belief was mistaken and so reported. The
servant afterward brought suit against the doctor for
assault upon the theory that his examination was only
submitted to through fear and dures. Upon the trial
a verdict was rendered in favor of the doctor. From this
court an appeal was taken to the Manchester Assizes.
The two justices who heard the question there disagreed
upon the law, Justice Lopez expressing his opinion that
the girl had only submitted to the examination
through fear of evil consequences that would follow her
refusal, and that her submission could not therefore be
considered a consent to the examination. Justice Lind-
ley, however, was of quite a different opinion, and
thought there was no evidence of want of consent as
distinguished from a reluctant obedience or submission,
and that, in the absence of all evidence of coercion and
mistaken from an order that she could have obeyed or
not, she had no cause of action. The court being
evenly divided, the judgment was allowed to stand.
An appeal was then taken to the court of appeals, the
justices of which agreed with Justice Lindley. The
appeal was accordingly dismissed and the judgment
permitted to stand in favor of the doctor. This
case is cited particularly for the purpose of pointing out a
possible danger. The mere beginning of a suit of this
sort, whether or not the plaintiff succeeds in obtaining a
judgment against the doctor, is greatly to his damage;
therefore he should never attempt an examination of
the kind unless the consent of the party to be examined
is fully and freely given.

Contagious Diseases.—Questions of liability of the
physician to his patients growing out of his conduct in
cases of contagious disease have arisen in two separate
and distinct classes.

The first and most important, which has been here-
tofore referred to, is that growing out of a breach of
duty on the part of the physician to protect his
patients in all reasonable ways from contagious and
infectious diseases. The liability of this class is very
well illustrated in the case of Piper vs. Menifee.† Here
the physician was told by the patient's wife that he had
taken a certain case of small-pox he must not come to
to see her husband. The physician said that "he would
not, unless the (small-pox patient) would be bound for
his fee." The next day, when he returned, the patient's
wife again told him that if he visited any small-pox
patients he must not come there. He replied that he
would not visit any small-pox patients. Ten days later
the patient's wife again pressed him strongly about
small-pox patients, again repeating the interdiction.
In answer he neither admitted nor denied that he had
visited such patients, but said that if he visited them he
would change his clothes, and there would be no dan-
ger. After the physician had been attending the
patient for about three weeks for typhoid fever, and
when he was getting better and began to recover from
the fever, he broke out with small-pox, and some time

* Contagious Diseases, New York Medical Journal, February 25,
1899, p. 280.
† Piper vs. Menifee, 12 B. Mon. (Ky.), 467, 54 Am. Dec., 547.

After the patient's son broke out with the same disease.
The patient also offered evidence to show that the phy-
sician was attending small-pox patients while attending
him. The court held that this statement of facts con-
stituted a good cause of action against the defendant.
Justice Marshall, who rendered the opinion, said:
"Suppose a physician, knowing that he has an infec-
tious disease, continues to visit his patients without
apprising them of the fact, and without proper pre-
cautions on his own part, and thus communicates the
disease to one of them. Clearly the physician thus
acting would be guilty of a breach of duty and of his
implied undertaking to the patient, which, whether it
be regarded in the light of carelessness or negligence
or fraud, would render him liable for consequent dam-
ages, including as well the suffering and danger and
loss of time as the expense necessarily occasioned by
the second disease thus produced by his own wrongful
act.

"The actual case, as presented by the evidence
which was offered, is even stronger for the (patient)
than that which has been hypothetically stated, in-
much as it may be inferred that the continuance of the
plaintiff's employment in the first disease was induced
by his promise not to visit small-pox patients while he
was visiting the (patient)."

From the very nature of the physician's professional
duties it is necessary for him to pass from patients suf-
ferring from infectious or contagious diseases of the
more ordinary and less virulent type to those not so
affected. Modern science has, however, shown that an-
tisepic precautions will greatly decrease the danger of
contagion, and if the physician adopts those measures
best calculated to insure the safety of those with whom
he comes in contact he will be considered as exercising
due skill and care as judged by the advanced stage of
the medical science.

The second class of cases in which the physician's
conduct has been questioned consists of those in which
he has incorrectly reported a patient to the board of
health as being afflicted with a contagious disease. In
this class of cases it seems that the question of liability
depends upon the good faith of the physician in making
the report rather than upon his skill and care. In pass-
ing upon a case of this sort Justice Sedgwick, of the
New York supreme court, said: "Nor, as I view the case,
can it be maintained that the defendants' (the physi-
cians') omission, if there were such an omission, to use
ordinary skill as physicians, in coming to their opinions,
was actionable under the facts in this case. There was
no improper or hurtful treatment or medication in
pursuance of the opinion. These opinions led them to
make an honest report to the health board. The stat-
utes had made it their duty to report cases of con-
tagious disease. The performance of this duty was not
part of the functions of a physician in his relation to
a patient, but rather to the public. My opinion is that
in order to give the public the protection due it, ac-
cording to the intention of the statute, any physician
that possesses in fact an opinion that a patient has a
contagious disease is bound to report the case, whether
he has or not used ordinary professional skill and know-
ledge. A physician of skill in everything but cases of
small-pox, which happily are not numerous, may, unex-
pectedly to himself, be called to a case which presents
him the appearance of small-pox. It may be said that
he can call in counsel. It can not, however, be
PITH OF CURRENT LITERATURE. [N. Y. Med. Jour.,

said that private counsel should be called in rather than such as the law has appointed. Certainly, if he really thinks the case to be one of small-pox, it is his duty to communicate his opinion to the public authorities, who furnish skilled physicians peculiarly competent to pass upon the case. They are the experts that the law points out for the physician. The attendance of those experts upon a patient can cause no injury, and therefore the responsibility rests solely upon the public officers.” *

It is evident that the logic of this opinion will not apply in cases where the act of the attending physician in reporting cases of contagious disease to the board of health is not a mere ministerial one, and where no regular physician is provided by law to make the examination by virtue of which the patient is quarantined. It is therefore believed that where a patient is quarantined by virtue of the examination of the attending physician he will be held to exercise ordinary skill and diligence in conducting that examination.

A case of liability arising from the conduct of a doctor in reference to a contagious disease, although not coming under either of the foregoing classes, or, in fact, growing out of a professional relation between the parties to the suit, is reported in the New York Supreme Court Reports. In this case a physician directed the plaintiff to whitewash a house in which there had been small-pox patients. The plaintiff objected to going into the house, but was informed by the doctor that the house had been thoroughly disinfected, and that no danger of contagion existed. Relying upon the doctor’s statement, the plaintiff performed the services and in due time broke out with the disease. This case came before the court upon a question of law. It was decided that the facts as stated showed a cause of action, and that it was for the jury to determine from the evidence whether the doctor had acted toward the plaintiff with due care and prudence, and whether the plaintiff had acted rashly and inexcessibly in entering the house under the circumstances.†

Negligence in Writing Prescriptions.—The physician may become civilly liable in damages as well for injury resulting from a negligently or ignorantly written prescription as from any other form of malpractice. Nor does the negligence of the druggist who compounded the prescription without discovering the error and directing the doctor’s attention to it relieve the physician from his liability.‡

*(To be continued.)*

Pith of Current Literature.

The Prophylaxis of Alcoholism in the Army.—M. Charles Viry, médecin principal de première classe (Archives de médecine et de pharmacie militaires, July), sums up a paper on this subject with the following conclusions: 1. The men should be taught by familiar and frequent discourse, by conferences, books, illustrations, inscriptions, etc., the dangers of alcohol, either pure or in combination, and an example of temperance should be shown to them. 2. The organization of canteens should be improved so as to transform them into places where the soldier can amuse or rest himself without the necessity of drinking. 3. The purchase of alcoholic drinks outside of the canteens should be interdicted as much as possible. 4. The sale in the canteens of every alcoholic liquor (fermented or distilled) before the morning meal should be forbidden. On the other hand, the sale, especially in the morning, of nonalcoholic stimulating or nutritious drinks, such as coffee, tea, chocolate, milk, etc., should be encouraged. 5. The sale of alcoholic liquors should be authorized in canteens only at mealtimes and during the hours immediately following. 6. The number of kinds of liquors sold should be limited, in order that a more efficient supervision over their quality may be exercised. 7. The sale in canteens of all alcohol insufficiently rectified should be prohibited. The examination as to rectification should be intrusted to special experts, and every effort should be made to prevent the sale of any alcoholic product other than those admitted after examination.

8. The price of non-alcoholic and of fermented alcoholic liquors should be lowered, while that of spirituous liquors, especially brandy, should be raised. 9. A rigorous surveillance over the execution of these orders should be instituted, and all transgression thereof, whether on the part of the men or of the canteen keepers, should be vigorously repressed, as well as all breaches of temperance. The recommendations here given have, we are informed, received the sanction of the general officer commanding the second French army corps.

The Mulberry as a Diuretic.—Lyon médical for July 30th, quoting Archives provinciales de médecine et de chirurgie for June, says that the use of mulberry leaves as a diuretic is very popular in Siberia. About forty-seven grains and a half are infused in a hot place for from eight to ten hours in two cupsfuls of boiling water. A cupful may be taken morning and evening. The savor of the infusion is said to be not disagreeable, and the remedy may be continued for three days. In one case the quantity of urine, from fifty-four ounces at the commencement, was gradually raised to sixty-two, seventy-two, and finally eighty-eight ounces. The patient was a man, of eighty-four years, who had suffered for ten years from edema of the feet.

Gonorrhœal Endocarditis.—Bjelogolowj (Bolnitscha Gaseta Botkina, No. 4, 1899; Clinica moderna, July 26th) concludes from personal observation of a case of gonorrhœal endocarditis, which terminated fatally, gonocci being found in the blood and in the endocardial inflammatory stratification, that the gonococcus, like the Streptococcus pyogenes, is able to give rise to a septicaemia, and that gonorrhœal endocarditis may develop in the course of a blennorrhagia without any affection of the articulations.

The Predisposing Conditions of Plague.—Dr. Atkinson (Lancet, August 5th), in his annual report for 1898 at Hongkong, says that the conclusions to be drawn from the colony’s experience of plague in 1896 and 1898 are that the occurrence of plague is favored by (1) long prevalence of drought or of abnormally low rainfall; (2) atmospheric temperature below 82° F., as the months of maximum mean temperature were in each year followed by a material reduction in the number of cases; (3) the absence of sunshine; and (4) the

---

† Span vs. Ely, 8 Hun, 255.
‡ Murdoch vs. Walker, 43 Ill. App., 590.
dampness of the atmosphere. During the months in which there were most cases the mean humidity of the atmosphere was high.

Fracture of Femur without the Usual Signs.—Dr. C. L. Starr, of Toronto (Boston Medical and Surgical Journal, August 17th), reported recently to the American Orthopedic Association a case occurring in a child of three years, in which, although there had been a fracture at a point just beyond the junction of the head and neck of the femur, as demonstrated at autopsy, there had been no pain or the usual signs, and a positive history of limping for only two weeks previously. After the post-mortem examination, the parents recalled the fact that only six weeks before the limp had developed the child had fallen from a high chair.

Curious Case of Spasmodic Urinary Incontinence during Coitus.—Dr. Paul Farez (Indépendance médicale, August 2d) recently reported to the Society of Hypnosis and Psychology the case of a woman, thirty years of age, married ten years, and the mother of two boys. In the early years of her married life she had been utterly devoid of all sexual desire or enjoyment, "cold as marble," to use her own expression; until one idle day she gave herself to a friend of her husband. For the first time she realized sexual passion, and thenceforth she became as sexually eager as she had previously been indifferent. In her the orgasm was accompanied by cries, by involuntary violent and uncontrolled movements, and often by loss of consciousness. Further, at the moment of the orgasm the woman ejected forcibly but unconsciously five or six jets of urine separated by an appreciable interval. This unpleasant characteristic was breaking up the domestic relations. The husband naturally lost all sexual attraction toward the woman, and contemplated taking a mistress; while the wife's sexual hunger was unsatisfied and she was tempted to look for satisfaction elsewhere. It was at this juncture that the woman came under Dr. Farez's care for other troubles, and the foregoing condition, with its attendant distressing circumstances, was only incidentally mentioned. The author recognized at once that his patient was a hysterics. For reasons which he describes, he realized that the urinary emissions were not due to compression of the abdomen during coitus. He elicited the fact that the woman had that neurotic tendency, by no means uncommon, of being unable to urinate on going to bed in her husband's presence, being compelled to rise later for that purpose when her husband was asleep. In the meantime coitus occurred with her bladder distended, and the contractions of the abdominal recti at the orgasm freed the sphincter. He succeeded in sending the patient into the hypnotic state, and suggested that she should urine abundantly at bedtime, and ordinarily immediately before coitus also. He also suggested control of the sphincter and moderation of the muscular crises at the orgasm. The treatment was entirely successful. The disgusting symptom ceased, and domestic harmony and happy marital relations were restored and continued at the time of the report.

Susceptibility versus Immunity.—The following admirable remarks of Sir Richard Douglas Powell (Lancet, August 5th) were made in the address in Medicine, on Recent Advances in Practical Medicine, delivered at the annual meeting of the British Medical Association. Sir Richard said:

"I am inclined to think that we are also coming to recognize better the third circumstance which renders virulent the specific microbe to its host. It has long been clear to every observant physician who has, on the one hand, even superficially kept in view the results of bacteriological inquiry, and who has thought upon the incidences of such infective diseases as he happens to meet, that we carry about with us in our accessible mucous tracts, and especially in our naso-oral and respiratory passages, amid other unconsidered trifles and as yet unclassified germs, samples of the organisms specific to many diseases. We are tenanted by these varied organisms from time to time in small colonies or singly, rendered inert only through want of opportunity. The very careful observations of Dr. St. Clair Thomson and Dr. Hewlett recorded in the Medico-chirurgical Transactions for 1895 show that there is a natural cleansing if not antiseptic secretion from the healthy nasal membrane which preserves it from contamination by the numerous organisms which abound in the nasal tracts, so that mucus taken from the central membrane of the nose in health may contain few or none. And as these mucus tracts are in a state of constant motion and from time to time obtain a temporary but abortive lodgment within us; virulent catarrh, diphtheria, pneumonia, influenza, tuberculosis, cysipelas, perhaps rheumatism, and probably in epidemic times some of the other infective diseases would be represented in one or other category among our domesticated or casual occupants. It is not, however, enough to have the poison germ on the one hand to acquire the disease on the other; there are intermediate or antecedent circumstances of dosage, acquired susceptibility, or that subtle malfunction of tissue in certain organs which is inherited and renders them weak in resistance to certain forms of attack. Let a period of depression come over us, involving some slight change in our blood or tissues, some local or general alteration in our chemical or vital functions, and one or other of these organisms may receive the opportunity for aggressive cultivation. We virtually know that this is so in the case of a common cold. Acquired by a momentary chill at an open door or through wet boots, such a catarrh becomes at once a highly contagious disease and will 'run through the house.' There can be no doubt that the catarrh is associated with the cultivation of an organism; it is equally probable that that organism must have preexisted in some part of the nasal surface. Does some vasomotory disturbance bring about the local conditions of increased heat and moisture needful for that particular form of microbe cultivation or is it merely depressed vitality that makes the host susceptible? No one, so far as I am aware, has yet condescended to work out the bacteriology of a common cold. Yet it is the type of a large number of more important diseases and carefully investigated it would, I believe, be fruitful in side-lights upon their etiology and prophylactic treatment.

"Dr. Washbourn, with whom I was discussing this question the other day, referred me to a most interesting and suggestive inquiry which he had made with reference to a case of recurrent catarrh, apparently simple. I must refer you to the paper, which is very short (being a single inquiry), for details, but I may briefly say that in an apparently simple coryzal catarrh a bacteriological investigation of the mucous discharges revealed the presence of characteristic influenza bacilli and of pneumococci. The patient, aged thirty-five years, had been subject to similar, or apparently similar, attacks
so long as he could remember. He had also had many recognized attacks of mild influenza and had been working at the bacteriology of pneumonia. There are many people of somewhat feeble vitality whose complaint is that they are constantly catching colds. Such attacks are due probably to the cultivation of successive erops of an ever-present organism. We have little power in attacking the organism; we might as well do battle with a sunbeam. Our treatment is to fortify the host, although, meanwhile, some local applications of a cleansing kind will in these, as in hay asthma, help to protect from the poison. Whatever the true bacteriology of a common cold may be, this humble malady is one of the most common starting-points of more important respiratory diseases, both as regards initial and secondary attacks.

Some few years ago I saw in consultation a medical friend who had pneumonia of a pyogenic type; but in response to my inquiry about drains I was informed that he had been in the house for some years, that he had a healthy family of young children, and that he himself had been in perfect health until he went out thinly clad on a cold night and got definitely chilled. He died after the lapse of a day or two, and on investigation a free communication was found to exist between the main drain and his surgery. This gentleman must for some months have been occupied by microbes which did not become operative under the control of a robust vitality until that vitality was temporarily impaired.

The tendency to rheumatism runs in families. It is hardly possible to conceive that chorea is not a manifestation of the rheumatic poison, which is most probably a micro-organism. A mental shock is the usual intervening aetiological factor in chorea, which presumably weakens the resistance of the nerve centres upon which the toxic influence falls. It is hardly possible that the mental shock and infection should have coincided in time; until more exactly informed we can only provisionally assume that the infective agent was indefinitely preexistent. This intermediate quantity in infective disease requires to be yet more carefully thought out in regard to measures of prevention and even of treatment. Much has been done by physicians in the last generation in general preventive hygiene with regard to the diseases then recognized as specific before their knowledge of the virus of these diseases was so accurate as now. More may yet be done if with the growing precision of our knowledge of the infective elements we maintain our inquisitiveness as to the conditions under which they become operative.

Unfortunately, we have not yet been supplied with any reliable antidote for the serum treatment of pneumonia. It was good-naturedly twitted by some of my friends in their criticism of a book published eight years ago because I did not speak well enough of the then recent observations of the Drs. Klemperer on the serum treatment of pneumonia; but in a paper read before this association in London five years later I could say no more, and to-day, although Pane’s antipneumocoeic serum will protect a donkey or a rabbit from the evil consequences of a strong dose of pneumococcus infection, it has not as yet come into practical use in the human disease. I have recently tried it in two cases without result. This may be due to three causes. In the first place, it is difficult to use the serum early enough in the disease, and, secondly, the most severe cases in which alone at present one feels disposed to try the remedy are most generally complicated with some other infection, so that the pneumococcus in the sputum does not signify the sole—perhaps not the most important—element of danger in the case. Thirdly, the doses employed by Pane have been very large, so large that one shrinks from introducing in such bulk an unknown or imperfectly accredited element into any case not already desperate. In the use of these very large doses my friend Dr. Charles, of Rome, has suggested to me the introduction of the serum per rectum as a method which he has known to prove efficacious with other serums, the absorption being rapid and the serum being unchanged. As yet, however, the serum can not be obtained in sufficient quantity for use in such large doses. In all probability the want of success, with casual exceptions, in the antitoxine treatment of erysipelas, puerperal fever, and allied affections, including infective endocarditis, may be similarly accounted for by the presence of more than one organic infection, thus requiring, as pointed out by Behring, Pfeiffer, and Kanthack, more than one antidote. I can not mention the name of Kanthack without deploring the loss which our profession and humanity at large have suffered through the early death while yet in full vigor and promise of work of this most able pathologist.

The Use of Formalin in the Treatment of Surgical Tuberculosis.—Hahn, of Mayence (Centralblatt für Chirurgie, 1899, No. 24; Edinburgh Medical Journal, August), says that a mixture of one to five per cent. of formalin in glycerin is very much more effective in the treatment of tuberculous joints, abscesses, and empyema than the commonly used emulsion of iodinol. He describes the results as quite remarkable wherever the formalin is able to come into direct contact with the tubercular tissue which it is desired to destroy. In tuberculous joints the best results are obtained when the articular cavity is distended with serous or purulent fluid, and the joints best adapted for its action are the hip and knee.

In dealing with joint or abscess cavities, the pus is first evacuated by a large aspirating syringe, if possible without giving rise to any bleeding; the cavity is washed out with boracic solution until the returning fluid is quite clear; as much of the one-per-cent. formalin glycerin is then injected as will correspond to one third or one half of the pus originally removed. There is marked reaction, with fever, pain, and swelling of the joint for a few days. Complete recovery may follow one injection, as described, or it may have to be repeated at the end of a fortnight. The cure may be interfered with if there are necrotic tuberculous masses in the joint or abscess cavity. Dr. Hahn does not claim to be able to cure all tuberculous joints by formalin injections, for a certain number of these are only amenable to direct surgical procedures.

Trikresol in the Treatment of Alopeia Areata.—MacGowan (Journal of Cutaneous and Genito-urinary Diseases, May; International Medical Magazine, July) claims to have found in trikresol a remedy of superior value in the treatment of alopecia areata. Eight cases treated by this application were cured within a period averaging two months and a half. The first application is preceded by thorough cleansing of the patch with benzine. The remedy is applied pure to the scalp, and in fifty-per-cent. solution with alcohol to the face. The patch and surrounding zone are thoroughly rubbed with a swab of cotton, saturated with the trikresol. The appli-
cation causes a burning pain, which disappears usually in the course of a few minutes. The area treated becomes thoroughly blanched, the whitish discoloration being followed in a few hours by hyperaemia. The applications are repeated in from four to ten days.

Proceedings of Societies.

SOCIETY OF THE ALUMNI OF THE CITY (CHARITY) HOSPITAL.

Meeting of April 12, 1899.

The President, Dr. William L. Stowell, in the Chair.

(The conclusion from page 238.)

The Use of Parotid-gland Extract in Ovarian Disease.—Dr. E. Pierre Mallett read a paper on this subject.

(See page 293.)

The President (Dr. William L. Stowell) said that to the general practitioner there was much in the paper that was new. As a society they were particularly fortunate, not only in having this clinical paper, but also in the gentlemen who were to take part in the discussion. They had with them Dr. Shober, of Philadelphia, who had already written so much on this subject—in fact, introduced it in America. It was with pleasure that he introduced Dr. Shober to open the discussion.

Dr. John B. Shober, of Philadelphia, said he felt gratified in having been invited to take part in the discussion of Dr. Mallett's interesting paper. He had been deeply interested in the subject for about a year and a half, and from his clinical experience he was convinced that we have very powerful agents in these glandular products, especially in the mammary and parotid glands. It was only clinical experience, however, based upon a limited number of cases. His attention was called to the subject by Dr. Bell's first paper, which was presented before the British Gynecological Society in 1896, in which he reported a series of cases of ovarian and uterine disease treated by the parotid and mammary glands. The speaker had the same results as Dr. Mallett in the use of the parotid gland in the treatment of ovarian disease. Patients with oophoritis, suffering constant ovarian pain, becoming worse just before the menstrual period, were promptly benefited by treatment with this gland. Enlarged, exquisitely tender ovaries rapidly decreased in size and could be palpated without causing pain. Cases associated with pelvic inflammatory disease, with adhesions and exudate, required operative interference. The speaker had not employed the parotid gland in such cases. Dr. Polk, of New York, had written so much about the use of the thyroid gland for menorrhagia and fibroids of the uterus that the speaker would only emphasize the fact that this gland seemed to act beneficially upon diseased epithelium wherever found, and it was this thought which first led Bell to use it in carcinoma of the cervix, a purely epithelial disease, and he reported some startling results. In a paper published in the International Medical Magazine for 1897, vol. i, entitled The Treatment of Carcinoma of the Uterus and of Ovarian Disease without Operation, Bell spoke of curing cases of carcinoma of the uterus by the use of the thyroid gland with curetage followed by tampons. In the speaker's experience in the use of the thyroid gland for menorrhagia and fibroids, the results obtained had been unsatisfactory. In some cases hemorrhage seemed to be controlled, but there were always associated great cardiac irritability and nervous depression, and he had long since abandoned the use of thyroid gland in these cases. On the other hand, the mammary gland, when given in proper doses, accomplished all that had ever been alleged for the thyroid gland in cases of menorrhagia due to subinvolution and in cases of fibroid tumor of the uterus, and the treatment could be carried on over long periods of time without causing any unpleasant systemic results. He had ten cases of fibroid tumors of the uterus, all of which were doing well; the tumors were diminished in size, the menstrual periods had become normal as to periodicity and quantity, and the general health had improved. Patients were able to bear certain doses of the mammary gland without having any untoward symptoms; but large doses had produced contracting pains in the tumors, and in cases where there were no fibroid tumors, large doses produced uterine cramps. Cases of menorrhagia from subinvolution, with flowing for seven or ten days at a time, responded promptly to treatment, and in the course of two or three menstrual periods they came down to normal menstruation; and the general health seemed to improve. He spoke of a patient of his, a woman, thirty-two years of age, who had had a large fibroid tumor resembling in size a nine-months' pregnancy, rising half an inch above the umbilicus. He used the mammary gland in that case, and in the course of a few weeks she reported that her general health was better, and that her next menstrual period did not come on until long after she had expected. It was three weeks before she began to menstruate again. In the course of a few months she was menstruating every twenty-eight days. During the time she was under treatment the tumor diminished in size. His experience showed that the mammary gland had a primary action upon the uterine muscle in some way, causing the uterus to contract. In conclusion, the speaker said that his personal experience seemed to show that the parotid gland relieved ovarian pain in certain selected cases, and that the mammary gland controlled hemorrhage from the uterus in fibroid and certain cases of menorrhagia by its power of stimulating uterine contractions. The diagnosis must be accurate and, therefore, should be made under an anaesthetic before placing a patient upon this treatment. If these remedies should come to be used largely by the general profession, the danger lay in inaccurate diagnoses, thus losing valuable time in cases which required immediate and life-saving operations.

Dr. Bache McG. Emmet said he had no experience with the use of these substances, and had been much interested to hear Dr. Mallett's paper and the remarks of Dr. Shober. He thought it necessary to go slowly in undertaking so new a thing. Dr. Bell, in his paper, in August, 1896, was exceedingly enthusiastic and stated unhesitatingly that he had cured malignancy of the uterus and had diminished fibroid uteri of the size of a seven-months' fetus down to a quarter of the size in a few months. While using the extract, however, he carried on the treatment that was well known to be beneficial, as had Dr. Mallett also, using uterine douche and ichthyol tampons, so that there had been no fair test made of these mammary, parotid, or thyroid extracts. Dr. Shober had referred to the effect of the thyroids upon the epithelial growths, and in view of
their known effect upon metabolism in myxœdema and kindred conditions, one might have great hope of witnessing their good influence over a much more extended range of disease. The speaker felt very conservative as to the benefits derived from these elements in uterine affections, and believed that they might have been obtained by other means employed in the cases recorded. The diagnosis was of great importance, and anybody might be mistaken at times; one would find an enlargement of an ovary, for instance, and think it a chronic disease, when perhaps it might prove to be only a normal enlargement of ovulation. He should never hope to obtain destruction of pelvic adhesions by any such method as this. Surgery would have to come to the rescue in those cases, and, as Dr. Mallett had observed, surgery had to be resorted to in many cases where he found the method under consideration was hopeless. Suggestion often had much to do with a patient's feelings after taking a remedy; the hope entertained that good was coming from the use of the medicine was instilled by the care with which the physician put the remedy before the patient.

Dr. E. H. Grandin said he knew nothing about these extracts from practical experience, and must pose as a skeptic. The years that had elapsed since he had devoted himself largely, lately entirely, to the diseases of women, had made him a skeptic. He began in the days when tampons, hot water, etc., were the remedies for many of the ills to which woman was heir, and he found through resort to these methods he could at best secure only palliation, never cure, of an organic disease of the pelvic organs. He then took up the use of electricity, and did not believe any one in this country had tested it more faithfully. Through electricity he often secured symptomatic cure, palliative cure, but never radical cure of any organic disease of the female generative organs. He had tested the thyroïd in fibroids, and his experience was exactly similar to that of Dr. Shober. He had obtained better results in fibroids of the uterus through a prolonged use of ergot, and from electricity, than he had secured with thyroïd, and yet to-day he would use neither, but would operate.

In regard to the cases reported by Dr. Mallett, he did not think that any of them in which relief had been secured beyond mere palliation were cases of organic disease. Where the appendages were diseased, bound down by adhesions, filled with pus or mucus, constricted in parts by adhesions, the ovaries sometimes filled with large blood clots or multiple cysts, he did not see how any drug, particularly these extracts, could possibly affect them. He did not question the fact that through the use of these extracts one might relieve the dragging sensations and in a measure the congestion, because he knew too well the careful observer who reported the cases, and the painstaking manner in which he reached his diagnoses; but for organic disease of the appendages he believed there was but one cure, and that was removal; because, if diseased, they were absolutely of no use to the woman and a source of pain. There was a vast difference between the reflex effect of the mammary gland (of the living) on the uterus and the giving of desiccated mammary gland by the mouth. When the child was applied to the breast there was contraction of the uterus, not because the woman was having extract inserted in her mouth, but it was simply the reflex effect of traction on the gland upon the uterus. Theoretically, one would expect mammary extract to cause hypertrophy instead of atrophy. Certainly the nursing infant thrived upon it! He was glad to find that those who had spoken were not enthusiastic on this question. What killed electricity was the enthusiastic way in which it was alleged to be a cure for each and every disease to which woman was heir. Those who tried these extracts were wise in reporting only palliation; but it should be remembered the same palliation could be obtained in these functional affections of the appendages through rest in bed and through regulation of the bowels. Physicians were often mistaken in their diagnoses. Abdominal surgery was full of surprises. One would make a diagnosis of a large fibroid behind the uterus, and find a dermoid cyst; or expect to find a small tube and ovary bound down by adhesions, and find instead a large pyosalpinx; look for disease of the appendages, and find a long vermiciform appendix. The danger of giving these extracts without first establishing an accurate diagnosis, which could only partially be made through examination under anaesthesia, was that while administering them the disease might be progressing, sometimes to the peril of the woman's life.

Dr. W. L. Baner said his experience with these preparations had been very limited indeed. He had used the mammary extract in one case, which was interesting in spite of the fact that it added absolutely nothing of scientific value to the subject. A little over two months ago a young unmarried woman had consulted him for menorrhagia from which she had suffered for three years, being unwell for twelve or fourteen days at each period, and losing a large amount of blood. During the last year a persistent metrorrhagia had been added, and she had become very anaemic. The uterus was very slightly enlarged and freely movable, and a small submucous fibroid was suspected. The patient had been taking a mixture containing ergot. Dr. Brooks Wells had examined her and had suggested that before operating hydragrasis should be thoroughly tried. The fluid extract had been given in large doses, but without any good result. Just about this time Dr. Mallett had mentioned his work in this direction, and it was decided to try the mammary extract. Five grains were given three times a day. It should be stated, as bearing on the psychic side of the matter, that the patient objected to taking any more drugs, as she had taken so many different things and none had ever done her any good. The next menstruation lasted only four days, and had not been followed by the usual spotting. The speaker said that he did not want to be understood as drawing any deductions. Perhaps the woman would return to-morrow or next day as badly off as ever, and have to be operated upon, but the circumstances had been interesting.

Dr. George H. Mallett thought they should testify as to the use of these extracts, not explain. Almost everybody would acknowledge that there was some influence on the pelvic circulation exerted by the mammary gland, and that the thyroïd gland taken by the mouth would affect the heart and also the pelvic circulation; for in cases in which the thyroïd glands had been removed these women had profuse menorrhagia. The mammary extract seemed to offer advantages over the thyroïd. In one case, that of a negro woman who refused to have her fibroid removed, the speaker gave her five grains of mammary extract three times a day. She refused to take the medicine, "would not take that stuff, it was worse than having a baby." She had the contractions. Ovarine was a valuable preparation; he
used it in cases following extraction of the ovaries with marked benefit, and also in cases of menorrhagie anemic girls without any iron; and in several cases in which the menstruation had not appeared for six months, after they took the medicine they menstruated. His experience in the work had been conducted with the writer of the paper, and the results coincided with his. Even though those patients were not cured absolutely, if they believed they were cured and continued to improve, what more could one want?

Dr. W. S. Stone said that the only experience he had had with any of these preparations was with ovarine. He had used it in, perhaps, a dozen cases and had obtained some favorable results, especially in those nervous symptoms that went with the artificial menopause. Perhaps one might form an opinion from the discussion that the treatment of pelvic diseases was hopeless, and resort to these extracts was absolutely necessary. It had been his experience at the Vanderbilt Clinic during the last five years that post-operative cases, for instance, were fewer in number each year, which, he thought, was one of the most interesting and hopeful things in gynecology. He thought one of the causes for it was in the better recognition of the septic condition of the uterus in many tubal and ovarian diseases, so that removal of the uterus, too, was oftener done. He had had no experience with the mammary or paraoid-gland extract.

Dr. E. Pierre Mallett said that he did not wish to be understood as stating that the paraoid gland would cure all forms and varieties of uterine disease. He had distinctly said in the first place that diagnosis was most important, and while he did not lay any claim to infallibility as a diagnostician, at the same time he had had a fairly good experience, often treating and examining these patients daily for weeks, months, and years; when these enlarged and tender ovaries would gradually seem to become smaller, and the patient would say that she was sure that she felt better, he did not know what more could be asked of any treatment. One speaker had said that he did not understand how any medicine taken by the mouth could affect cases of radical disease of the appendages, and that he thought these cases could be cured only by radical operation, in which the writer of the paper entirely concurred; but, as great stress was laid on diagnosis and no purulent cases had been mentioned, the point had no bearing on the subject. Another of the speakers thought that rest in bed would probably have cured many of these patients; possibly it would, but rest was one of the methods of treatment that were unapplicable to the clinic patients; they could not rest in bed, so either had to keep around and attend to their duties or go to a hospital, and they naturally wanted to keep out of the hospital as long as possible. In regard to pelvic massage, the speaker thought it was a most valuable means of treatment in these cases, notwithstanding the disparaging remarks of some of the gentlemen, and he was of the opinion that if used with discretion and skill in the proper cases, its effects were readily appreciated in liberating bound-down and adherent uterus and appendages. He admitted enthusiasm in regard to these extracts, but thought that his results had warranted it, and felt sure that any one using them as he had done would feel the same way. He did not think that it would cover the entire gynecological field, but it would certainly seem to be worthy of a careful investigation.
Miscellany.

Suggestions for Improving the Efficiency of the Army Medical Service.—Dr. W. H. Devine, lieutenant-colonel and medical director, second brigade, Massachusetts Volunteer Militia, late major and brigade surgeon, United States Volunteers (Boston Medical and Surgical Journal, August 17th), in a paper recently read before the Massachusetts Medical Society, makes the following suggestions, some of which have been practically adopted by the Massachusetts Volunteer Militia, and which are recommended for adoption by the entire national guard:—1. That professorships of military medicine be established in every reputable medical college. 2. That until such time as professorships are established, the State provide a course on required subjects. 3. That physical examination of officers and men be made mandatory. 4. That troops at State encampments conform as nearly as possible to duties required in service on the field. 5. That every medical officer receive commission. (This pertains to contract surgeons.) 6. That one or more men in every company be detailed for regular instructions in ambulance corps, to prevent possibility in the future of the country losing the service of men especially trained for this service. 7. That one medical officer be selected in each regiment or brigade for his surgical ability. 8. That a corps of trained female nurses be organized in every State. 9. That divisional hospitals, in the broad sense, be abolished, and that small brigade and divisional hospitals be established for special cases, such as surgical and contagious. 10. That the volunteers follow, as closely as practicable, the regular army, so that when called into service together the two branches may work in harmony. 11. In addition to the present instruction in ‘first aid,’ a course in prevention of contagious diseases, etc., be given. 12. That a reserve staff of medical officers be formed in each State; said staff to be composed of ex-members of the medical department of the national guard.”

The Canadian Medical Association will hold its thirty-second annual meeting in Toronto on Wednesday, Thursday, and Friday, August 30th and 31st, and September 1st, under the presidency of Dr. L. H. Cameron. In addition to the president’s address (on Wednesday afternoon), there will be an address in surgery, on The Radical Cure of Hernia, by Dr. William B. Coley, of New York (on Thursday afternoon), and an address in medicine, on Infant Feeding and Infanteile Diarrhoea, by Dr. J. T. Fotheringham, of Toronto (on Friday morning). The list of papers announced is as follows: The Best Method of Dealing with the Consumptive Poor, by Dr. E. J. Barrick, of Toronto; Floating Kidney Simulating Disease of the Ovaries and Tubes, by Dr. A. Lapthorn Smith, of Montreal; Observations on Adenoids and Enlarged Tonsils and their Removal, with Notes of Eighty Cases in Private and Hospital Practice, by Dr. D. J. Gibb Wishart, of Toronto; The Methods and Ultimate Results of Operations for Halux Valgus, by Dr. N. A. Powell, of Toronto; Report of a Case of Abdominal Pregnancy, by Dr. H. Meech, of London; An Experience in Formaldehyde Disinfection, by Dr. F. Montizambert, of Ottawa; An Inquiry into the Etiology of Chronic Bright’s Disease, by Dr. A. G. Nicholls, of Montreal; Operations for Extra-uterine Gestation, by Dr. W. H. Chown, of Winnipeg; Tuberculosis in Canadian Cattle, and its Prevention, by Dr. J. George Adam, of Montreal; The Hospital Room in Each Dwelling, by Dr. W. J. Telfer, of Montreal; The Treatment of Spina Bifida, by Dr. George A. Bingham, of Toronto; Complications and Treatment of Fracture of the Skull, by Dr. J. M. Elder, of Montreal; Recurrent Paralysis of the Third Nerve (Chareot’s Ophthalmoplegia), by Dr. W. J. G. Kerling, of Montreal; Tuberculosis and Insurances, by Dr. J. H. Hume, of Toronto; (a) Typhoid Infection without Intestinal Lesion, (b) Gas-tropoisis, by Dr. A. McPhedran, of Toronto; Some Observations on the Treatment of Cancer, by Dr. A. R. Robinson, of New York; Gall-bladder Surgery, by Dr. J. F. W. Ross, of Toronto; The Etiology of Typhoid Outbreaks, by Dr. Wyatt Johnston, of Montreal; The Treatment of Cataract, by Dr. R. A. Reeve, of Toronto; Christian Science, by Dr. J. H. Richardson, of Toronto; Anesthesia by Chloroform and Ether, by Dr. W. B. Jones, of Rochester; The Treatment of the Acute Digestive Disorders of Infancy, by Dr. A. R. Gordon, of Toronto; Rhinolitits, by Dr. Hubert D. Hamilton, of Montreal; Observations on the Relations of the Thyroid Gland to the Uterus, by Dr. C. R. Dickson, of Toronto; The Question of Operation on Thyroid Tumors, by Dr. George A. Peters, of Toronto; A Case of Malignant Disease of the Gall Bladder Simulating Hydroperosis (Feeding Through the Gall Bladder for Three Days), by Dr. F. N. G. Starr, of Toronto; Cooperation of Surgeon and Physician in Abdominal Cases, by Dr. A. L. Benedict, of Buffalo; Nephrolithotomy, by Dr. B. L. Riordan, of Toronto; The Mastoid Operation in Chronic Middle-ear Disease, by Dr. J. M. McCallum, of Toronto; Ringworm in Toronto, by Dr. Graham Chambers; The Great Lakes as a Health Resort, by Dr. E. H. Adams, of Toronto; A Case of Subcutaneous Emphysema, by Dr. Frederick Fenton, of Toronto; Craniectomy for Microcephalus (with patient), by Dr. W. J. Wilson, of Toronto; Curettage, its Use and Abuse, by Dr. R. Ferguson, of London; Notes on a Case of Jacksonian Epilepsy with Operation, by Dr. D. Campbell Meyers, of Toronto; Massage and the Relief of Eye Strain in the Treatment of Glaucoma, by Dr. George M. Gould, of Philadelphia; Extreme Emaciation in Hysteria, with Notes of a Case, by Dr. T. Beat, of Winnipeg; Hydrotherapeutics in the Treatment of Disease in Children, by Dr. A. D. Blackader, of Montreal; Results Already Achieved at the Gravenhurst Sanitarium, by Dr. J. H. Elliott, of Gravenhurst; The Successful Treatment of Three Important Cases by my Combined Form of Treatment, by Dr. G. H. Burnham, of Toronto; A Case of Morbus Caræuleus appearing at Thirty-four and unassociated with any Abnormal Condition of the Heart, by Dr. W. B. Thistle, of Toronto; The Etiology and Treatment of Eclampsia in the Parturient Woman, by Dr. C. J. C. O. Hastings, of Toronto; Cyst of the Broad Ligament, by Dr. Charles Smith, of Orangeville; The Internal Staff in Modern Hospitals: a Comparison of the American and Canadian Systems, by Dr. F. Leonard Vaux, of Ottawa; Erysipelas, with Treatment by Marmorek’s Antitoxine, by Dr. A. de Martigney, of Montreal; Report of Three Surgical Cases (Cancer of the Stomach, Angeiosarcoma of the Ovary, and Splenie Abscess), by Dr. Norris Worthington, of Sherbrooke; Surgery among the Insane—its Difficulties, its Advantages, and its Results, by Dr. A. T. Hobbs, of London; Pneumothorax from Gas-producing Bacteria, by Dr. Frederick G. Finley, of Montreal; and Gunshot Wound of the Intestine, by Dr. N. E. McKay, of Halifax. There will be a pathological ex-
The Military Medical Service of Germany.—Dr. Alexander Ogston (Lancet, August 5th), in the address on Surgery on The Medical Services of the Army and Navy, delivered at the annual meeting of the British Medical Association, said: “Although the arrangements of foreign services can not be directly adopted in our own, much which is instructive may be learned from the medical services of Germany, where, of course, compulsory service exists. In that empire every medical man who has served possesses a fixed military rank, even if engaged in civil practice, and is liable to be called upon to serve where and when required. Those who have not served in the regular army but are in private practice receive annually an inquiry addressed to them by the war office as to whether they are prepared to serve their fatherland in case of war. Every German medical man who has served in the army at all is maintained for nineteen years under military orders—that is, he possesses a fixed rank and is allotted, even in time of peace, a known military post which he would occupy if war broke out. Thus the university professors hold high military rank corresponding with their eminent civil position and scientific attainments, and are required to give annual courses of instruction to the medical officers serving in the army or navy. Such well-known surgeons as Bergmann, Bruns, Trendelenburg, and Mikulicz have to teach these classes during the Easter holidays so as not to interfere with the winter and summer sessions of the universities. Each professor has his fixed military rank assigned to him in case of war; most of them rank as lieutenant-generals, some as generals, and even higher, and in the event of war they act as consulting surgeons to the medical officers of the army in the field or base hospitals. They receive the same pay as the military surgeons, as do also the other surgeons who are liable to be called out in case of war, and some of the latter have places assigned to them in the sanitary corps, etc., so that their skill and experience are utilized in every department of the service.

In time of peace German army surgeons have the development of their professional culture insured by the following measures: The most promising surgeons and assistant surgeons are sent to do duty for a year at a time in the medical, surgical, and gynecological departments of the hospitals connected with the universities and in other large public hospitals unconnected with them. The junior and assistant surgeons are also annually sent to attend the special courses of instruction in anatomy, surgery, and operative surgery mentioned above. The senior medical officers, nearly corresponding with our surgeon-majors, at least the most competent and promising of them, have to serve in rotation in the large military hospitals in which are treated not merely soldiers but all kinds of ordinary patients; there they have to act as teachers and attend and take a share of the tutorial work among the pupils in the classes of the various professors; or they may be sent to do duty for a year in the general hospitals not only in the surgical but also in the medical and gynaecological wards. They have also to attend, as they may be ordered, annual courses of bacteriology, or they may be furnished with funds for traveling in other countries and studying their medical and sanitation arrangements. All surgical instruments and appliances in the German army are provided by the state, and in their navy this is likewise the case; every hospital in which the medical officers serve has its complete armamentarium provided for it, so that no unwise economy hampers the most thorough and modern practice of the healing art, and the same thing is true in regard to their naval medical service.”

The Military Medical Service of Russia.—Dr. Alexander Ogston (ibid.) said: “In the Russian army and navy similar care is taken of the professional culture of the medical officers. Russia possesses six large and three hundred small hospitals connected with the army, besides smaller lazarettos; and in some of these the equipment is far in advance of anything the services possess in this country. Thus the military hospitals of St. Petersburg, wherein are treated all medical, surgical, gynecological, ophthalmic, and other diseases, consists of five separate clinics or infirmaries, each of which is complete in itself and possesses departments for every class of disease and even wards for paying patients. The wards are excellent and replete with appliances of every kind; and there are bandage rooms, purifying rooms, operation theatres, bacteriological departments, rooms for physical research, laboratories for teachers, and laboratories for students, all excellent and complete. Each clinic possesses eight hundred and fifty beds, a hundred and twenty of which are for women's diseases and twenty for children's; and about forty-five thousand patients are treated per annum. In these clinics the students and assistants have to work in the most thorough manner and study every kind of case. The hospital possesses a staff of thirty-four professors, seventy privetim docentes, and forty-seven assistants. Each department is furnished with an ample annual allowance for instruments and apparatus and can apply for, and obtain additional grants for anything more that is required or for anything new and expensive. They have liberal provision of everything calculated to assist the most advanced work and investigation—X-ray rooms, photographic rooms, electrical rooms, immersion lenses, centrifuges, etc., to an extent that excites the marvel and envy of British visitors. The work in the wards, such as case-taking, temperature-recording, and every sort of examination and study of the cases, is of the very highest character, and the operations and dressings are carried out by the surgeons and qualified assistants in a fashion that is above praise.

"Russia has three thousand surgeons in her army, and any of these, may, if he show ability and powers of work, obtain an order to return to study in the hospitals for a period of two years. There he has to work as a regular assistant and on proving his capacity may attain a place among the teachers of the institution, or he may be transferred to the hospital of some provincial city and there continue to perfect himself in his profession and further qualify himself for his duties in time of war. The Russian naval hospitals are arranged
like their army hospitals; they exist in many parts of the empire, there being five large ones at different ports besides one or two smaller ones; they admit civil cases of all kinds, and in them the medical officers possess opportunities of training themselves in all manner of high-class professional work. In the Russian navy the medical officers who show ability can obtain permission to return for two years to the hospitals and can there advance by merit, ten every year, to become privatim docentes and so proceed to the position of professor; and they have the same privilege as those of the army of obtaining after ten years' service two years of study leave in the hospitals and schools, during which time they are granted extra pay. The Russian state supplies its army, its navy, and their hospitals with instruments of the newest construction, embracing appliances for special diagnosis and treatment; the operation instruments, and even the boxes that contain them, are arranged so that they may be readily sterilized by heat or otherwise; and Schimmelbusch's sterilizers and apparatus specially constructed for carrying out antisepic and aseptic treatment under the difficulties of a campaign are supplied with them. The drugs are prepared for the services in the form of tabloids with the active principles accurately dosed and made up by the newest machinery. Dressings, bandages, and such like are prepared, sorted, made up, sterilized, and sent up from factories which are ideals of purity, ingenuity, and care in a way that is an example to the world."

The Military Medical Service of France.—Dr. Ogston (ibid.) stated that in the French army post-graduate courses expressly for medical officers are conducted by professors at the different universities throughout the republic, and the cost is borne by the army medical department, while a certain number of the medical officers of the active and reserve army are every year ordered to attend them, extra pay being drawn by those who do so.

A Good Thing Mother was at Home.—The Journal of Medicine and Science for August quotes the following from the Sanitarian:

"Well, Maggie," asked a teacher of a little girl, "how is it you are so late this morning to school?"

"Please, sir," was the reply, "there was a wee bairn cam' to oor house this mornin'!"

"Aha!" said the teacher, with a smile; "and wasn't your father very pleased with the new baby?"

"No, sir; my father's awa' in Edinburgh, and dinna ken aboot it yet; but it was a guid thing my mither wis at hame; for gin she had been awa', I wadna hae kent what to dae wi' it."

The Lane Medical Lectures.—According to the Boston Medical and Surgical Journal for August 10th, the Lane Medical Lectures for 1900 will be delivered at the Cooper Medical College, San Francisco, by Professor Michael Foster, of Cambridge University.

The Characteristics of the Medical Profession.—

Lord Rosebery (Lancet, August 5th), in an address at a prize distribution at Epsom College, England, a college founded especially for the sons of medical men, referred in well-chosen terms to the medical profession. The Lancet, in an editorial, says: "The point of view from which he approached this branch of his subject may have struck some of his hearers as novel. The men among them not members of the medical profession may have expected to hear it associated with the triumphs of science or the alleviation of suffering, to which latter, indeed, Lord Rosebery referred. The schoolboy destined for it may have had various inducements to contemplate it or may have had it selected for him, but neither man nor boy probably thought of it as requiring 'more stubborn and obdurate courage than any other,' or of a member of it as 'fighting one lifelong battle in which he knows that he must be beaten' in a profession that is 'one long struggle in which, like the Englishman, he must never know when he is beaten until victory has gone against him,' and which 'in its essence contains, perhaps, the most supreme elements of manhood of all the profession.'"

A Third Attack of Typhoid Fever.—M. Pérochaud (Gazette médicale de Nantes, July 23d) records a case of a third attack of typhoid fever in a man forty-eight years of age. The attack proved fatal.

The American Association of Obstetricians and Gynaecologists, we learn from the American Journal of Obstetrics for August, will hold its twelfth annual meeting in Indianapolis on Tuesday, Wednesday, and Thursday, September 19th, 20th, and 31st.

A Pension for a Distinguished Physician.—According to the Lancet for August 5th, her Majesty's government, on the recommendation of the governor-general of India in council, has conferred on the distinguished physician Sir Joseph Fayrer, as a reward for distinguished and meritorious service, a pension of £100 per annum.

Death of Professor Balbani.—The Tribune médicale for August 2d announces the death of Professor Balbani, the embryologist, of the College of France, at the age of seventy-seven.

The Case against Christian Science.—The North American Review for August contains an admirable article by W. A. Purrington with the foregoing title. The author deals in this article with the absurdities displayed in Mrs. Eddy's two books, Miscellaneous Writings and Retrospection and Introspection, in the same trenchant manner as in an article on Christian Science and its Legal Aspects, in the March number of the same review, he dealt with her Science and Health, with Key to the Scriptures. In the present article the commercial and mercenary side of Mrs. Eddy's cult is elucidated in her own words, as its follies and pseudo-scientific inanities were exposed, also in her own words, in the former one. The article deserves to be widely read.

The International Congress of Gynaecology and Obstetrics, held at Amsterdam from August 8th to 13th, had under special consideration the four following important subjects: 1. The surgical treatment of fibromyomas. 2. The relative value of antisepsis and of perfection of technique in the actual results of operative gynaecology. 3. The influence of position upon the form and dimensions of the pelvis. 4. The indications for Caesarean section considered in relation to that of symphysiotomy, craniotomy, and prematurely induced labor.

Congenital Anosmia.—According to the Riforma medica for July 28th, Placzek recently showed to the Medical Society of Berlin a woman, fifty years of age, who had had complete anosmia from birth, and could not recall ever having perceived any odor of any kind.

THE SPHERE OF LARYNGOLOGY.
THE PRESIDENT’S ADDRESS.*
BY WILLIAM E. CASSELBERRY, M.D.,
CHICAGO.

Fellows of the American Laryngological Association: In response to an invitation by Dr. Frank H. Davis, of Chicago, this association was organized at Buffalo as early as June 3, 1878, the first annual meeting having been held in New York in 1879. Years of progress, honor, and success have elapsed, and we are now assembled on Lake Michigan’s shore to open our twenty-first annual congress in the city of our founder. I extend to you on behalf of the residents, on behalf of the medical profession, and especially on behalf of your own colleagues of Chicago, a most cordial welcome to the Garden City of the West.

These have been active years; a long series of volumes, each containing the transactions of an annual meeting, attest the scientific and progressive value of our labor. Many of the names therein contained are those of men who caused American laryngology, for a time, to lead the world. I feel constrained to mention thus the brilliancy of our record for two reasons: First, that it may serve as a stimulus for the years to come. See to it, fellows, that our exertions now and in the future equal those of the past. Let not the light of our enthusiasm be dimmed and ever cherish a loyalty to this association, which will induce you to present before it the results of your best endeavor. I mention it, secondly, in order that you may realize my own appreciation of the honor which you have bestowed in asking me to serve for the year as your presiding officer.

The honored custom of an address from the chair affords opportunities for suggestion looking to the welfare of our organization and of the department of medicine which it represents which would not find expression in any set paper or formal discussion. All are doubtless conscious of recent changes wrought in laryngological practice by the advance of nasal pathology and by the inclusion of the ear in the sphere of work. From a physician treating affections of the throat and chest the laryngologist is fast becoming a surgeon with a routine of practice limited to local measures as applicable to the upper respiratory tract alone. While freely conceding that progress has been realized along local surgical lines, I deprecated the tendency of the day to deal with the throat and nose exclusively in a mechanical way, as if they were organs detached. I believe it engenders narrowness of thought, and that, through habitual disuse, there is gradually lost to the physician much of that fundamental knowledge of pathology and applied therapeutics which is so essential to the welfare of the patient. Not quite two decades ago my attention was attracted to diseases of the throat and nose, in part by reason of the neglect which they at that time suffered, but more because of their intimate relationship to general medicine, affording an opportunity to specialize and yet to remain in touch with the practice of medicine as a whole. In practice at that time the consideration of laryngeal conditions was closely linked with pulmonary diseases and internal medicine.

A few had ever then awakened to the real importance of nasal pathology in connection with certain throat symptoms, and ere long the nose had many devotées, its importance in laryngology being signalized, unnecessarily, perhaps, but without protest, by the twin designations “throat and nose,” “laryngology and rhinology.” But soon there were nasal enthusiasts whose idea of the subject, entire, seemed to consist in the establishment of a wide patency of the nostrils. They introduced the reversed designation “nose and throat,” meaning to emphasize thereby a subserviency of throat affections, which I think scarcely exists to the degree implied. Perhaps you may recall Michael’s parody, a humorous song, written for the Berlin International Medical Congress of 1890:

“Es tröstet über manches Leid
 Uns die Philosophie,
 Doch heilen kann zu jeder Zeit
 Nur die Rhinologie.
 Stets wird die Nase angebracht,
 Denn das hilft immer, wie bekannt.”

In derogation of our specialty one is occasionally reminded by cynical friends that “there is nothing to it but boring a hole through the nose,” a grotesque misconception which is quite widespread in the profession, and for which, I fear, these same nasal enthusiasts are largely responsible.

The intimacy of the ear with the throat and nose is conceded. Acute suppurative otitis and chronic suppuration, through recurrent acute attacks, are so often complications of primary nasopharyngeal infections, and chronic otitis media is so far an outgrowth of rhinitis, septal deformities, “adenoids,” etc., that the laryngologist has the treatment of aural affections actually thrust upon him. Even the patient’s discernment convinces him that the laryngologist’s skill and equipment are the means best adapted to the end. And having appropriated the ear, one should cultivate an exhaustive knowledge of the organ, but as an addition to laryngological lore, not as a substitute for a part thereof. Aural enthusiasts have developed among laryngologists whose commendable studies of the ear have been a help, but who centre their attention so forcibly upon that organ as to convey the impression of neglect of funda-

* Read before the American Laryngological Association at its twenty-first annual congress.
mental laryngological precepts. Their disposition to subordinate the throat is evinced by such “departmental ditties” as “ear, nose, and throat,” “otolaryngology,” “otorrhino-laryngology,” etc.

Add to these our confrères in smaller towns who find it expedient to group together the eye, ear, nose, and throat, and who encompass numbers who to-day are posing as laryngologists whose education, interests, and restricted routine of practice put them out of touch with important medical and systemic phases of the subject.

Do latter-day laryngologists as a class habitually endeavor to establish the real diagnosis in the earliest demonstrable stage of pulmonary tuberculosis? Are not such patients liable to come first before us with their irritable throats, hacking cough, tendency to hoarseness, and inclination to rhinitis? Suppose they are ready to believe, and sometimes even to insist, that they have only “throat trouble” or “catarrh,” are they not entitled to an exhaustive examination with a view to the earliest possible discovery of tuberculosis when present, or are they to be satisfied with the conventional spray, laryngeal injection, or series of nasal cauterizations? I recall instances in which failure to deal adequately with such cases became a reproach to the laryngologists consulted, and unnecessarily so, for the requisite knowledge and skill are only exceptionally lacking; but a disposition is shown to become enchained by a limited office routine and to permit the hasty incidental to the crowded hours of the day to serve as an excuse for deferring a more searching investigation extending to the organs of the chest.

Now, it is not alleged that the laryngologist need embrace in his practice the whole broad field of chest diseases, but it is urged that he be ready to apply all the arts of diagnosis and that he be conversant with every resource known to medicine in the treatment of pulmonary conditions for the benefit of cases of laryngo-pulmonary tuberculosis, laryngo-bronchitis, bronchial asthma in association with ethmoiditis, and other conjoined pathological conditions of the upper and lower respiratory tracts.

For the purpose of diagnosis, he should acquire and retain by practice a perfection in the art of physical examination of the chest, should possess ready means of establishing the ratio of height to weight and the relation of height to thoracic perimeter and vital capacity. He should note the conformation of the chest, the temperature, and pulse rate, be familiar in a practical way with the bacteriological technique for tubercle bacilli, and ready with the use and interpretation of the tuberculin test. Familiarity with the upper respiratory tract serves as an aid in the diagnosis of pulmonary states. Slight laryngeal infiltration, disclosed only by the laryngoscope, may afford the earliest suspicion of pulmonary tuberculosis; the presence of nasal polypi and polypoid degeneration of the middle turbinated bodies, unassociated with sinus empyema, will aid in the exclusion of tuberculosis in favor of bronchial asthma or chronic broncho-pneumonia; while a critical inspection of the throat will at times afford a satisfactory explanation of symptoms, such as cough or haemorrhage, which might otherwise be attributed to lung disease. Hence, the laryngologist is naturally qualified best of all to disclose the earliest stage of tuberculosis, or to exclude it, if he will but embrace his opportunities and look below the larynx as well as above it.

Nor will it answer to omit attention to the heart, aorta, and mediastinal contents. Paralysis of a vocal cord through pressure on the recurrent nerve by an aneurysm is a simple proposition, but more complicated ones which require a high degree of diagnostic skill are continually encountered.

Regarding the treatment of pulmonary conditions, especially tuberculosis, cases which are not complicated by affection of the throat are naturally claimed by the department of internal medicine. It is not possible, nor even desirable, to draw an absolute line at this point between laryngology and internal medicine; in practice they are bound to overlap; but, conceding that if drawn anywhere it would be here, there remains a considerable proportion of pulmonary cases in which the upper respiratory tract is so far implicated that they fall naturally under the care of the laryngologist. Hence, as before said, he should be conversant with every resource known to medicine in the treatment of pulmonary states for the benefit of cases of laryngo-pulmonary tuberculosis, laryngo-bronchitis, bronchial asthma in association with ethmoiditis, and other conjoined pathological conditions of the upper and lower respiratory tracts. He should be a good systemic therapist, and continue to cultivate the art of prescribing, realizing the uses as well as the limitations and abuses of internal medication. As yet only disappointment is the fruit of serum therapy in tuberculosis, but one should follow closely the literature, for every day fresh knowledge and a deeper insight are gained into the subject of immunity, and the discovery of an effective tuberculosis antitoxine may yet be hoped for. But, above all, one should study the conditions of natural immunity and susceptibility in order that, having made an early diagnosis, one may direct the mode of life and place of abode best adapted to arrest the disease and overcome the susceptibility. This implies a ready familiarity with sanitation, hydrotherapy, climatology, and sanitarium resources and methods. From the Alps, the Adirondacks, and the Rocky Mountain region come encouraging reports of the curability of incipient pulmonary tuberculosis, reaching as high as seventy per cent. under a sanitarium régime which secures abundance of fresh air, sunshine, and suitable food; but we get little convincing information concerning climatic effects upon laryngeal tuberculosis. While Heryng, Krause, Gleits-

---

mamm, and others have demonstrated the value of surgical measures in suitable cases of laryngeal tuberculosis, there are yet so many which are unsuitable for this line of treatment that one turns with gratification to the reports of Solly* and Levy † from the Rocky Mountain region to find that unmistakable laryngeal tuberculosis in the proportion of twenty per cent. recover in that climate, and that another twenty per cent. lives along indefinitely, greatly improved. That dryness and altitude were formerly thought to be inimical to laryngeal tuberculosis was probably based upon the unfortunate fact that advanced cases do badly under any conditions. Carefully studied reports from other resorts would be welcome and laryngologists at large should thoroughly familiarize themselves with the principles of climatology, in order intelligently to serve their patients who in despair beg for advice, and who otherwise will wander over the face of the earth on recommendations of lay friends and at the behest of hotel agents and railroad advertisements.

In connection with bronchial asthma, studies in nasal pathology have furnished gratifying information concerning the associated polyoid changes in the ethmoid region, and they tend inferentially to establish a vasomotor defect as the common cause of both the nasal and bronchial symptoms. Pronounced relief, and often a practical cure, may be effected by nasal treatment, but the ethmoiditis tends to recur, and prolonged observation and repetition of radical measures are essential to the best results. This the laryngologist is much more likely to secure if he show himself willing and ready to assume full charge of the case, attending not only to the nasal surgery, but exhausting the pharmacopoeia and climatic resources to bring the fullest measure of cure or relief.

For a familiarity with bacteriological technique there is a constant need in the practice of laryngology. F. de Havilland Hall, in the Lettsomian Lectures, and others have emphasized the importance of the throat and nose as portals of entrance of the micro-organisms of infectious diseases. The scientific application of bacteriological principles enabled Behring and Roux to snatch from Nature herself the crowning achievements of the century—diphtheritic antitoxine. The hunt for the Klebs-Loeffler bacillus is already popularized and its importance in the diagnosis, especially of tonsillar infections, duly recognized. The search for the Cannon-Pfeiffer bacillus of influenza and for the micro-organisms of pneumonia should be reduced to the same practical basis. The patient who applies for treatment feeling ill, together with sore throat or cold in the head, and who receives the routine spray and perhaps some rhinitis tablets, only to become bedridden in a day or two with severe influenza or lobar pneumonia, has a just complaint again the laryngologist for failing to make a more searching investigation into his condition at the start. In the words of the late Harrison Allen, “We shall be raised in our esteem in the degree that we add a little more science to our art.”

All laryngologists are familiar with the many throat conditions which appear as salient features of underlying systemic states, and yet, in the overswing of the movement toward localism, general pathological data, systemic therapeutics, and hygienic aids are not always utilized to the utmost. I have only to mention briefly the difficulty of controlling the excessive secretion of simple chronic nasopharyngitis without hygienic aids; the systemic defects, especially digestive derangements, which commonly underlie chronic pharyngitis; the laryngeal lesions of arthritis deformans, and the pharyngeal discomforts of rheumatism, diabetes, and gout. How often is edema of the larynx merely secondary to chronic nephritis, and laryngeal ictus simply the forerunner of locomotor ataxia! Indeed, I might enumerate indefinitely associated throat and systemic states, but I have said enough. I think, to support the contention that the laryngologist should continue, as of old, to be first of all a good physician, and after that something more, a specialist.

Nor need a man with this breadth of view be any less skilled in the operative technique of amygdalotomy, in the correction of deviated septa, the surgery of the collateral sinuses, and the mastoid operation. He can appreciate the disadvantages of nasal obstruction just as well as another who perceives that only.

Gentlemen, we are assembled here to aid one another in the search for more truth; let us profit by each other’s experience, search along liberal lines, and endeavor to realize Emerson’s conception of power: “A cultivated man, wise to know and bold to perform, is the end to which Nature works.”

IS THE SO-CALLED AMERICAN VOICE DUE TO CATARRHAL OR OTHER PATHOLOGICAL CONDITIONS OF THE NOSE?*

By JOHN W. FARLOW, M. D.,
BOSTON.

The so-called American voice is so often referred to that I think we are justified in making inquiry as to its nature and cause. It is never spoken of in complimentary terms—quite the contrary—and our liability to nasal catarrh is considered to be the determining cause. I think we are all agreed that it is the exaggerated nasal quality, the production of the voice in the nose, the twang, which is its most noticeable characteristic, and we can omit consideration of the larynx and faucæ as factors. It is not the thick, muffled voice

* Solly. Medical Climatology, p. 147.
† New York Medical Journal, July 20, 1895.

* Read before the American Laryngological Association at its twenty-first annual congress.
of weak carrying power, such as occurs in cold in the
head, but the high, penetrating, vibrating voice, in-
dicating an openness of the nasal chambers, so that
the voice made in the larynx finds its way into the
nose.

Any condition which hinders the passage of air into
the nose, such as large tonsils, adenoid disease, post-
nasal polypi or tumors, enlargement of the posterior
ends of the turbinals, tends to diminish the nasal reso-
nance, and hence should not be considered as contrib-
uting to the production of a nasal voice. When we say
we “talk through the nose,” we mean that we do not
speak through but in the nose, and we may distinguish
between the sound made when only the very anterior
part of the nose is obstructed (as when the nostrils are
closed by the fingers) and when the obstruction in-
volves the turbinals, as in acute coryza; the former
sound approximating more the nasal twang.

The marked nasal sound we should expect might be
produced when there is obstruction in the anterior
part of the nose, as by deviations or spurs of the
cartilaginous septum—which impede the free es-
cape of air, which is thus made to vibrate abnor-
manally in the nasal chambers. A blocking up of only
one nostril might be sufficient. A nose very small and
narrow at the tip, especially if this bends sharply down-
ward, might produce the same effect. Again, enlarge-
ment of the anterior ends of the turbinals or anterior
polypi might act, to a less extent, in a similar manner.
As regards obstructions in the posterior portion of the
nasal cavities, their effect would be to hinder the en-
trance of air into the nose, and thus prevent nasal vibra-
tion. The same may be said of adenoid or other hyper-
trophies in the postnasal space, the well-known effect of
which is to deaden the voice.

Let us now consider the effect of chronic catarrhal
conditions of the mucous membrane of the nose with-
out hypertrophy, so often associated with a similar
disease of the postnasal space. In severe cases of long
standing there may be anesthesia and paresis of the
soft palate, which would diminish the proper activity
of the muscles which shut off the fauces from the post-
nasal space, and thus some of the tones which should
be made in the mouth are involuntarily formed higher
in the nose and acquire a nasal character. This is
well known to occur, temporarily, immediately after
the removal of a large adenoid, before the palate has
regained its proper strength.

Apart from the effect of the incomplete movement
of the palate, I do not see that an atrophic condition
of the nose tends to make a nasal voice if the method
of speaking is correct. If it is incorrect, the nasal char-
acter should be more marked, owing to the greater op-
portunity for vibration.

For purposes of study, we may divide our patients
roughly, according to age, into—

1. Children up to twelve years.
2. Those from twelve to thirty years old.
3. Those above thirty years.

I think there can be no question that the nasal voice
is very common in our first class. The voices of young
children at play or in the class room are often very no-
ticeable for their nasal quality. But if we refer to the
list of conditions which I have enumerated above as
possible factors in the production of the nasal element
we shall find little justification for it. Deviations of
the septum are decidedly uncommon in young children,
polypi are almost unknown, the paretic condition of
the palate hardly exists, and hypertrophies of the tur-
binates, although common enough, are more likely to
occur as enlargements of the whole length of the tur-
binals, together with hypertrophy at the pharyngeal
vault. So that we are allowed to infer that an age
which furnishes very many examples of nasal voice has
but little in the nose to cause it.

From twelve to thirty years of age we find an in-
crease in the number of cases of obstructing septa and
anterior turbinal hypertrophies. Polypi are more com-
mon, and atrophic rhinitis, with some paresis of the
palate, is also more frequent. I should say that the
nasal voice was met with very often at this age, but not
more frequently than in the preceding period, and cer-
tainly not proportionately to the increase in the caus-
tive conditions.

After thirty years of age the various pathological
conditions continue, and the sclerosing inflammations
of the mucous membrane become more marked. About
the frequency of the nasal voice, my impression is that
it is rather less common than earlier in life, perhaps in
the sense that there is a larger proportion of voices
with no nasal intonation, although there are many very
marked examples of the nasal twang; while in
the young those who speak without any nasal twang are
decidedly fewer.

In a general way, I should say that, considered
from the standpoint which I have referred to above, we
were not justified in thinking that the condition of the
nose was the important factor in determining the nasal
voice. In fact, I feel sure that the members of this
society would be unable to classify their patients’ voices
into nasal and non-nasal by mere examination of the
nose, unless, perhaps, in some cases of marked septal
deviations. I do not, of course, allude here to the kind
of voice produced by acute coryza, marked general tur-
binal hypertrophies, etc., where the voice is deadened
and nasal respiration obstructed.

If we are correct in the opinion that the condition
of the nose is not the principal factor in causing the
faulty voice, we should certainly expect to be able, in
many cases, to improve the manner of speaking with-
out medical or surgical treatment of the nose. Many
excellent singers have throats and noses which are far
from normal, and pathological conditions have more to
do with the range and power of endurance of the sing-
ing voice than with its proper quality in the medium registers and when used in moderation.

A boy eight or nine years old was brought to me for a very nasal, twangy voice. There was some deflection of the septum nasi, but otherwise the nose was in excellent condition. I was asked if correction of the septum would take away the disagreeable quality of his speech. I knew a number of his playmates and noticed that nearly all spoke in the same way. I told his mother that if his companions continued to speak as they now did it would be only natural for him to imitate them whether his septum was straight or crooked.

The following year he went to a school in another country, and when I next saw him I found that his nasal voice had almost entirely disappeared, while his septum remained as before.

A theological student from a small country town consulted me with reference to the removal of a septal spur which caused him some discomfort in breathing at night. His voice had quite a marked nasal twang, and he tried to get me to assure him that after the removal of the spur his voice would improve very much. I told him I could relieve his breathing, but would have to resort to other measures about the voice. The removal of the spur was followed by freer breathing, but no particular change in his voice took place until after a course of exercises in the proper manner of placing and using his voice in speaking.

These are merely examples to show, one, the effect on the boy, without operation on the nose, of removing him to a school where he had no nasal voices to imitate, and the other, the effect of voice training in the young adult after an operation had failed.

On the other hand, if we examine some of our best speakers and actors we shall find that they very often suffer from the same pathological conditions of the nose as those who have poor voices. I have in mind a public speaker with clear voice of great carrying power without effort. I had always supposed that he was the possessor of unusually good vocal organs, but I found a very bent septum, and also a number of polypi.

A clergyman with absolutely no twang and a wonderfully good speaking voice, had a very marked obstructing ridge of the septum with turbinal hypertrophies. He had learned to speak well before these latter appeared, and their presence, although causing him some discomfort in breathing, were without appreciable effect on his voice. Such cases are common in the experience of you all, and are not exceptional cases of the few who are able to surmount what most are unable to overcome.

The anterior obstructions of which I have spoken are common in all civilized races, and there is no reason for thinking that any peculiarity in the American voice is due to what is possessed by others equally with ourselves. The parts of our country where are the oldest centres of civilization and education should be the places where most attention is paid to both the singing and the speaking voice, and this is probably the case. But in our old country villages, distant from the populous centres, the voices of the natives are well known to have the nasal twang without regard to the conditions of the inside of their noses.

It is not at all surprising that the presence in many parts of our country of so many recent immigrants from Europe, many of them entirely uneducated, should make us so accustomed to all sorts of pronunciation of English that we are, to a certain degree, indifferent to the importance of correct methods of speaking. There is plenty of evidence that pathological conditions of the nose are very common, but they are not more numerous in places where the voices are nasal than elsewhere, and there is no question but what training of the voice, especially in childhood, will do more to improve the speech of the coming generation than treatment of the nose. In September our daily papers are filled with notices of singing teachers, but for every one who aspires to sing there are one hundred who use the voice for conversation only. These latter are content to speak after the manner of the community in which they live, and no thought is given as to whether this is a proper manner or not.

OBSERVATIONS ON THE TREATMENT OF HAY FEVER.*

By BEAMAN DOUGLASS, M.D.

Adjunct Professor of Laryngology in the New York Post-Graduate Medical School and Hospital; Pathologist and Assistant Surgeon, Manhattan Eye and Ear Hospital (Throat Department).

About the vicinity of New York the experience of that special form of disease or irritation which we call hay fever was specially unfavorable during last August and September. There seemed to be a veritable invasion of the disease. I do not know whether the special irritant was unusually present or severe, or whether the noses of the sufferers happened to be abnormally involved, but it was apparent that in old cases the patients suffered severely, and new cases were more numerous than we have seen for many seasons.

Perhaps some one has, from his observation or experience, developed a new theory of the disease; perhaps he may care to express his recent impressions; perhaps some line of new treatment has been tried successfully in the past warm months. If these points are brought out here, if the subject can be clarified by exchange of experience and discussion, the few moments this paper requires will not be foolishly wasted.

One can not in a short paper, or in a single evening, review all the therapeutic measures introduced for the relief of this troublesome disorder, or even touch at all in detail upon the salient theories of pathology or atiol-

DOUGLASS: THE TREATMENT OF HAY FEVER.

The times of suffering are about the same, the severity of the symptoms is equal, the sequelae are alike, and the difference is mainly one of condition of the nasal cavities.

The cases in which there are no discoverable nasal lesions are in the minority. We remark that the patients are not robust, are generally in poor health, suffer from forms of neurasthenia most of the time, or complain of attacks of rheumatism, asthma, or gravel. They have sometimes vasomotor disturbances elsewhere and suffer especially from hives.

We say they are nervous patients or uric-acid sufferers, or what not, but we do not explain the cause of the disease. Perhaps you can tell me why I can enjoy immunity from this disease, can inhale dust of all kinds, can revel in flowers, roses, and asters, although suffering considerably from the results of a nasal catarrh and a well-developed hypertrophy of the middle turbinated body, and my patient with no recognizable lesion can not enter my office where flowers are arranged without developing instantly a nasal vasomotor paralysis which congests the turbinate bodies and brings on coryza and conjunctivitis. Why does my housekeeper, who has no nasal lesions, as we commonly understand them, suffer every sweeping day all the symptoms of hay fever from this dust, while my patients with well-organized synesthesia, ecchymoses, and other pathological lesions never mention dust irritation?

Here is a stumbling-block which must be explained away before we proceed. We must try to understand why hay fever may develop without any recognizable nasal lesion. It will help us in treating the disease. Rhinologists will answer you that some lesion must be present to complete the causative chain and say it is made of three links—viz., a special irritant (pollen), a nasal lesion, and a debilitated or neurasthenic patient. This is undoubtedly true in a large majority of all cases. There still remain cases with one link broken and no discernible nasal lesion. It seems that the cause must lie in that great nervous system of which we have much still to learn. A few common instances may help us to explain this class of cases. You are all familiar with the fact that preputial adhesions can cause serious general convulsions; that an injury to the little finger can make the whole hand ache; that a sharp, circumscribed blow upon the shin is felt over the entire leg and thigh, and that an irritation of a dental filament can cause general neuralgic conditions. These are all common examples of a special sharp or inflammatory irritation of a terminal nerve filament causing disturbance far outside itself. Why is it not possible for some filament of the extremely sensitive nasal nerves by its reflex action to produce all the vasomotor disturbances which we call hay fever, especially if this nerve is in a hypersensitive state from general constitutional conditions, and at such times meets the special irritant of dust or pollen or smoke? Here, I think, is a fair
explanation of the manner of development in hay-fever cases without recognizable lesion in the nose. To account for the extremely irritable condition of these nerve filaments we can at once assign as special irritants the various classes of internal derangements accompanied by blood disturbances, uric acid, rheumatism, absorption of improper products of digestion, etc. Authors have always maintained that uric acid played an important part in the production of hay fever; others, that rheumatic conditions did the same.

It is quite a comfortable classification to recognize, then, that there are cases of hay fever due not to any special disease of the nose, but caused by an irritant acting from outside upon nerve filaments made hypersensitive by nervous exhaustion accompanied by loss of vasomotor balance, or by nerve filaments irritated to disturbance from materials exuding from the vascular structure in the nose. There at once we can classify all the cases caused by digestive, uric-acid, or rheumatic conditions under the one class of "vicarious elimination."

The histological structure of the nose makes this theory extra plausible when we remember that the secreting power of the nose is quite remarkable. There is in other organs a secretion from the glands, but in the nose there are not only millions of glands secreting constantly, but a seous and watery exude is furnished to the tissues direct by the special erectile tissue (the turbinated bodies), and, besides, lymph exudes through microscopic lymph channels upon the surface of the mucous membrane.

The cases of hay fever presenting nasal lesions are in the majority. It is easy to understand that nerve filaments have acquired a hypersensitive condition as the result of any inflammatory change in the nose; also, that points of nasal tissue in contact, or adherent, give rise to disturbances of circulation, these to congestion, and afterward to leukocytic infiltration and new tissue formation. It is not difficult to see that exostoses, ecchondroses, polypi, and enlarged turbinated tissues act as foreign bodies upon a very sensitively nervous organized tissue. And it is not difficult to believe that the removal of these irritants results favorably for the relief of hay fever. Only remember that after the recognized pathological conditions have been removed an irritable condition remains which demands consideration.

The treatment of this malady must be considered under four different divisions, to wit:

1. A treatment of the cause. (a) Local irritant, (b) vicarious elimination, (c) vasomotor sensitiveness, (d) neurasthenic conditions, (e) uric-acid diathesis.
2. A treatment of the attack. (a) Local, (b) general.
4. A treatment between attacks.

The attacks of hay fever are produced by the effects upon the supersensitive or diseased nasal mucous membrane of irritating particles in the atmosphere derived mainly from the exhalation of pollen of certain plants. This irritating activity resides in the products not only of the ordinary dried hay, but in the living plant, which throws off the pollen in large quantities. The timothy grass, *Ambrosia artemisiifolia*, stench grass, broom grass, honey grass, foxtail, gladiolus, ailantus, rose, aster, chrysanthemum, triticum, sea kale, and avena have been cited as causative in this affection, and Blackley attributes the hay-fever production to seventy-four separate forms of pollen. All patients are not susceptible to irritation of the nasal membrane and the subsequent hay-fever symptoms from each one of the seventy-four kinds of pollen, but suffer from a special irritation from one or several varieties. If possible, these patients should by observation determine which plants are active in their cases, and should move, during the pollen-producing period, to a region where these forms of plants do not grow. Great altitudes are generally beneficial, and certain regions are reputed free from pollen, especially the White Mountains. Some patients do well on sea islands about twenty miles from the shore line. Very susceptible membranes are irritated enough to produce an attack whenever ordinary floor or street dust is inhaled. A respirator has been devised to place over the mouth and nose, and some relief is experienced if this is worn in the street. This respirator is more commonly worn in England than here. A dampened towel or handkerchief folded to two thicknesses and placed over the nose and mouth will thoroughly filter out all the irritating particles from the air, and forms a ready means of preventing the attacks from house sweeping and dusting. It must not be removed until all the particles of dust are deposited from the air.

Remember that blood charged with noxious elements of imperfect digestion, and chemical substances at present unrecognized and unknown, tends to rid itself of this material in the nasal mucous membrane. The deposit of this material acts upon irritated nerve branches and produces the symptoms of vasomotor disturbance. This vicarious elimination must be regarded as a possible cause, and all the other organs of excretion must be stimulated to do better work. The proper amount of exercise must be insisted upon, the diet arranged with simple but nutritious food, and the regular action of the bowels attended to. If vicarious elimination is considered in any particular case as causative, the diet should be scant, with solids for three days, after which small quantities of white meat and some cereals may be used.

Vasomotor disturbances or disturbances of circulation, manifested by easily taking cold, blueness, pallor, or blushing, cold hands and feet, and palpitation of the heart, must be treated by cold sponging every morning, cold baths, and cold spinal douches, and the circulation
steadied and regulated by small doses of quinine and digitalis.

Neurasthenic conditions are also a cause of hay fever, and must be combated by exercise, rest, change of occupation, iron, quinine, and strychnine. A long list of nerves, so called, has been recommended for the neurasthenic condition in hay-fever patients, but my experience is that the drugs to use are exercise, rest, and change of occupation and environment. Bosworth, however, speaks of belladonna, zinc, arsenic, phosphorus, hydrocyanic acid, valerian, bromides, and opium—a long list, which I mention only to condemn, especially the use of opium in any form.

If uric acid or rheumatism is suspected to be the causative element in a case of hay fever, proper means of elimination of the irritant must be considered. It is generally recognized as a cause by the patients, who have noticed that the rheumatism comes on or the urates or uric acid appear in the urine rather regularly, either before or after an attack of hay fever.

Of great use in this class of cases are saline purgatives, Turkish or hot baths productive of profuse sweating, the rapid elimination by means of diuretics (potash, digitalis, water, and lithia), together with a carefully arranged diet list, such as for gout and rheumatism.

Formerly the only relief possible for the sufferer from this troublesome malady was to reside during the entire period of this disease in a place where he was not affected by the irritation causing the attack. The great expense, deprivation, and interference with his business or home duties often prohibited his absence, and he went through the days, until frost appeared, a very great sufferer and very ill. The treatment of the attack has been advanced so far to-day that patients need no longer seek a residence in the hay-fever resorts during the pollen season, but may remain at home, and with constant attention run through the hay-fever period with only enough sickness to make them feel wretched or somewhat weakened and depressed. The local symptoms, discharge, sneezing, asthma, headache, etc., can now be controlled and the general symptoms combated with success. The treatment of the attack resolves itself into a local and a general treatment.

The local desiccata in the office treatment are: 1. To cleanse the membrane of irritating pollen or mucus and pus. 2. To relieve the hypersensitiveness of the over-irritated nerves. 3. To restore the tone of the overdistended blood-vessels and cause their shrinking and the shrinking of the mucous membrane.

The home treatment of the local condition should be directed to keeping down the irritation, restoring the blood-vessel tone, and protecting the nasal membrane.

The constitutional treatment of the attack consists of preventing the vasomotor dilatation and combating the unfavorable general symptoms.

To cleanse the nasal membrane we may use a douche. If the douche is used quite warm (106° F.), or even hot (114° F.), it also fulfills the second requirement and relieves the supersensitiveness of the membrane and contracts the blood-vessels. The douche is used as follows: As a preliminary to its use, the nose is gently sprayed with a watery one-per-cent. cocaine hydrochloride solution, which slightly contracts the tissues and, by partly anesthetizng the nose, permits the use of hotter water. The douche bag is filled with hot water, and in it is dissolved enough salt to prevent any exosmosis from the tissues; one drachm to one pint sodium bicarbonate may also be added in the same strength if any adherent mucus refuses to come away. The bag is placed six inches above the level of the bent head, and before and during the douching the patient must breathe freely through the mouth. If the head is well bent over and all breathing is carried on by the mouth, the water will simply run from the douche nozzle into the nose around the septum and flow out the opposite side. The slightest desire to swallow should be avoided, and if the water refuses to flow freely from the opposite side to its entrance the nozzle must be at once changed to the other side. In case the patient desires to blow his nose the douche must be checked, all free water allowed to flow out, and the nose blown with both sides free, and neither side closed with a handkerchief. If these details are properly attended to not a drop of water will enter the frontal sinuses, the antrum, or the Eustachian tubes, and all ill effects of the nasal douche will be avoided. Two quarts of water should be used for its cleansing and contraction effects, and after complete drying, by gently blowing, the second indication may be fulfilled.

The nose is now treated with that most valuable remedy for hay fever, cocaine. A four- or six-per-cent. solution is used to obtain a distinct therapeutical effect—viz., to relieve the supersensitiveness of the overirritated nerves and to contract the overdistended blood-vessels. This remedy is applied only on cotton pledges, packed cautiously against the obstructing parts, left in place four minutes, and removed. If any unpleasant effects of cocaine are perceived, the patient is given whisky or digitalis or aromatic spirits of ammonia in full doses. Of course, it is distinctly understood that this cocaine is administered in the office treatment and never in these strengths at home. I am also particular about the douche, and prefer to use it only when directly under my own observation, until the patient has learned how to safely use it. After the cocaine has been used the supersensitiveness may be further treated by means of some slight cauterizant, the effect of which will last for several hours. There are three remedies safe to use in this condition, and they are best applied to the nasal mucous membrane on pledges of cotton or by spray.

Silver-nitrate (ten grains to one ounce) solution is useful, but causes some reaction and burning.

Phenol camphor (two thirds camphor, one third carbolic acid) is slightly cauterizant and useful. The remedy of greatest use is Clark’s solution, composed of—
DOUGLASS: THE TREATMENT OF HAY FEVER.

Sept. 2, 1899.

R Mercury bichloride .................... gr. j;
Quinine hydrochloride ................. 3j;
Glycerol of carboxic acid (B. P.) ....... 3j.

M.

Douglas recommends more active cautery of the sensitive area by drawing lightly over this area the knife of the electro-cautery. I can not believe anything useful of this procedure.

The home local treatment consists of using the hot douche, as described above, whenever the physician is certain that the patient can use it without danger to his ears or accessory sinuses, together with the introduction afterward into each nasal cavity of the following soothing protective:

R Cocaine (alkaloid) .................. gr. ijs.;
Zinc oxide ................................ 5j;
Bismuth subnitrate ...................... 5ss.;
Albolene (liquid) ...................... 3j.

M.

Shake and use with a medicine dropper every two hours; after the very acute symptoms have subsided we may substitute an oily spray as a protective to the mucous membrane. A favorite formula and a non-irritating one is—

R Menthol .............................. gr. ij;
Eucalyptol ............................. gr. j;
Benzoal ............................... 3j.

M.

The general treatment of the attack is very important, for by this means we control the action of the vasomotor nerves and relieve the attacks of over-distention of the erectile tissue of the turbinate bodies. Acetanilide, digitalis, and quinine, the first used cautiously, the other two in full doses to produce physiological effects, act admirably upon the vessel tone and relieve the constitutional symptoms from which patients suffer so severely. The most important remedy to use internally is one rather new in therapeutics, but its use seems to be established beyond a doubt. I refer to the internal administration of the dried suprarenal glands. I can not speak over-enthusiastically of the beneficial and apparently specific effects of this remedy when administered in full doses. Without exaggeration, I may repeat that it is in my experience almost a specific for the symptoms of hay fever, and a remedy to safely and surely restore the over-distended condition of the nasal erectile tissue.

I have never been courageous enough to use it without giving the patient at the same time all the relief to be obtained from local treatment, but it has acted so promptly and so regularly that I have been sorely tempted to abolish local treatment and depend upon it alone. The remedy is used either alone upon the mucous membrane by means of a spray, a watery solution of the glycerin extract being employed, or it is given internally, such as the powdered dried suprarenal glands compressed in tablets. Used either way, the effect seems to be equally prompt and successful, resulting in a very satisfactory vasomotor condition in the course of twenty-four hours and a thorough control of the disease in forty-eight hours. The tablets are given to adults every two hours day and night until some prostration, giddiness, or palpitation is felt, or until the local examination of the nasal membrane shows that the remedy is controlling the vasomotor paralysis; then, with the cessation of the discharge, the relief from irritation and sneezing, and when the partial restoration of the nose as a respiratory organ is accomplished, the dose is given at longer periods—every three hours, then every six hours, then twice daily—and the administration of two tablets a day is continued throughout the hay-fever season. If disagreeable symptoms reappear because the dose is too rapidly diminished, the dosage may again be increased until the symptoms are controlled.

If used in a spray, the nose is treated every three hours. While the use of the remedy is yet in its infancy, I may be premature and unwise to sound its praises so roundly. The fact remains, however, that it in some way marvelously controls the vasomotor nerves of the nose; that there is a marked reduction in the size of the turbinate bodies, with wonderful lessening of irritability, and an almost complete cessation of the coryza and sneezing; that an improvement in the conjunctival condition can be observed by the physician in less than forty-eight, and sometimes twenty-four hours; and that under its continued administration the patient remains in comparative comfort during the remainder of his attack.

With the onset of frost the serious work upon the noses of those presenting any lesion must begin. Deviated septums must be straightened; contacts, synechias, and polyps must be relieved; congested areas must be cauterized, adenoids and tonsils treated, and, in fact, the entire nasopharyngeal tract investigated and all pathological conditions cured. The details of this work would indeed fill a book, and have no interest for us now, except to remind us that the results of such work, if carefully done, are most gratifying. Indeed, you may expect to cure a majority of your patients permanently of attacks of hay fever by surgical work upon the nasal interior. When heredity plays a rôle in causation the cure is hopeless, although in these hereditary cases the attacks may be rendered less severe.

The Color of the Hand in Malaria.—Dr. Albert L. Bennett, writing from Libreville on the Congo (Colorado Medical Journal, August), has on several occasions noticed a peculiar bright pink coloration of the skin covering the thenar and hypothenar eminences of white men resident on the west coast of Africa. In most of these cases the pink color appeared consecutively to recovery from an attack of hematuric (“black-water”) fever. Dr. Bennett wonders if physicians in the Southern States of America have noticed this coloration of the hand in association with malaria.
BOVINE TUBERCULOSIS
IN ITS RELATION TO MAN.

By EDWARD MOORE, M. R. C. V. S.,
ALBANY.

This subject is a story old—older than many of the hills and valleys that beautify the landscape to-day, older than some of the islands of the sea. I speak of its antiquity because in this country bovine tuberculosis was rarely recognized until 1890. The disease in cattle has been described in veterinary works, printed mainly abroad, under such headings as tubercle, consumption, wasting, pining, and scrofula; also called angle berry and grape disease by butchers, because of the knotty growths found by them in affected carcasses, and it has been known to veterinarians abroad for a great many years; yet our stock papers, agricultural journals, veterinarians, and the American public generally gave the subject no importance prior to the year above mentioned. I searched the volumes of the Country Gentleman for ten years prior to 1890, and, outside of articles by the author of this paper, the subject was not mentioned until December 19, 1889, when it was stated that “cattle tuberculosis seems to be spreading on the continent of Europe, according to the statistics produced before the Veterinary Congress lately held in Paris. Of cattle slaughtered in public abattoirs, more than one per cent. were found affected with the disease.” One might search back to the landing of the Pilgrims in vain for information on this subject prior to 1888. At a meeting of the New York Farmers at the Metropolitan Club, February 18, 1896, Mr. Theodore A. Havemeyer said: “I have been for a long time a breeder of cattle, as was my father before me. Up to 1888 I think tuberculosis was not known by my father; up to that time it certainly was not known by me.” The organization he was speaking to is composed of about eighty of the wealthiest and most representative men in this country, who own high-class stock farms. Every member had large sums in pure-bred cattle, and was vitally interested in all such subjects, and, although many of them had had tuberculosis in their herds for years, they did not know it. The medical profession up to this time was in no way exercised over the danger of the communicability of tuberculosis from the bovine to the human race, nor, indeed, did they lay much stress on the infectiveness of the disease from person to person. Then suddenly all America was stirred by articles from veterinarians, physicians, and laymen. Later, laws were enacted, cattle commissions appointed, inspectors were sent out, herds were subjected to the tuberculin test, and animals that gave satisfactory reactions were killed. Many physicians went to see post-mortems, were convinced of immeasurable dangers, and fell into line. Stock owners trembled and the public was in a panic, and saw more danger in milk than in rum. The tidal wave swept over the country; State and local boards of health, medical and veterinary medical societies, agricultural societies, farmers, grangers, dairymen, milkmen’s associations, and the nail-keg and soap-box aristocracy of the country store were all discussing the “new” disease in cattle and its relations to man. The disease, however, was not “new,” in fact, is one of the oldest, but it was new to most of the people and it served as a great scare. It was treated as if it were a most desolate scourge just imported into the country, when, as a matter of fact, it was no more prevalent in proportion to the number of cattle than it had been.

Legislative Appropriations for Stamping Out.—The chief aim of health boards heretofore has been to destroy tuberculous cattle; the greater the number condemned and slaughtered, the greater the glory. No matter that it struck consternation into the ranks of the proprietors of a great industry. No matter that in many cases the richest blood of heredity in pure-bred herds was forever lost—lost though it had cost lifetime and fortunes to obtain; lost through the wanton, needless, insatiable thirst for a big killing bee. What did it matter that a great paying institution employing many hands was wiped out; that the proprietors were financially ruined; that employees were thrown out of work; that great farms were deserted? Slaughter was the war cry. Salvation they dreamed not of. If it were proved that our people contracted the disease from the cattle, I would heartily favor such slaughter. Or from the cattle-owner’s standpoint I would favor it if assured that the undertaking were practical, and that its cost would not be too exorbitant, and that the infection could then be kept out of the State. The framers of the laws under which the inspections have been made and the members of the State boards of health seem to have given no thought to the immensity of the task, or the expenditure such a plan entails. If they have, we have not been told how they propose to succeed. The yearbook of the Department of Agriculture for 1897 states that the government has made and distributed to State authorities sufficient tuberculin to test fifty-seven thousand cattle. The census of 1890 gave New York State alone 2,131,392 cattle. How much tuberculin would be needed then to examine the cattle in all the States? The United States Government reports for 1897 placed the number of milch cows at 18,113,000; other cattle, 32,647,000. Total valuation, $877,169,414. If we could wave over this State a fairy wand and thus instantly banish all bovine tuberculosis, how long would the immunity last, while the remainder of this vast country is full of infection, and the bacilli can retain their vitality for months in a bale of hay, and the winds can blow them over the borders? I know of a stock farm where $100,000 was spent for farms and buildings, and $30,000 for pure-bred cattle, and in about a year these cattle were disposed of at any price on account of the methods pursued by the State in which the farm is located. Tuber-
MOORE: BOVINE TUBERCULOSIS IN ITS RELATION TO MAN.

Bovine tuberculosis in man, and such of the lower animals as are susceptible to it, is generally recognized as a specific infectious disease due to the tuberele bacillus, and this bacillus in either species is considered as practically the same. We are interested in this paper with tuberculosis in the human and bovine species, the two great families in both of which it exists to an alarming extent. The disease occurs in a limited way in several of the domestic animals other than the ox, but assumes very little practical importance so far as they are concerned. The disease is a slow and insidious one, wholly different in this respect from such diseases as cholera and small-pox of the human, or cattle plague of the bovine. Tuberculosis in cattle does not necessarily kill; on the contrary, many animals maintain ordinary health and high condition, apparently suffer no inconvenience from it, and finally die of some other cause. In other instances there are signs of constitutional disorder with more or less of the symptoms common to it, and in acute cases followed by death within a few weeks or months.

Breed.—All breeds are susceptible. It has been erroneously believed that Jersey cattle were most prone to tuberculosis, but the royalty bred and the common scrub are alike subject to it, just as the various races of men are.

Sanitation and Spontaneity.—The old writers gave as some of the causes of tuberculosis bad ventilation, filth, and insanitary conditions generally. No combination of ill conditions can produce a single case of the disease, nor can the most perfect and elegant buildings and hygienic surroundings offer immunity from it. Of course, this is easily accounted for now that the means of infection are understood.

Heredity.—Dobson, quite an authority a few years ago, in his work on the ox, says: “There seems to be no doubt as to the hereditary character of this affection, so that in no case should a bull be chosen from stock which are thus diseased. . . . A report to the parliament of Victoria, New South Wales, in 1886, says that heredity certainly plays a most important part in the propagation of the disease.” This is the opinion of about all veterinary writers. Since the discovery of the tuberele bacillus, and the application of the tuberculin test, it has been found that calves from tuberculous dams, if removed immediately after birth from all chances of infection, rarely show disease. Heredity has but small claim to attention now.

Predisposition.—We have been assured by all writers that predisposition and conformation were most important factors. We know to-day that no matter how narrow-chested and weak constitutionally an animal may be, tuberculosis can not occur without infection, and it does not seem to select the puny ones especially.

Contagion.—We have seen that most of the old ideas about tuberculosis have been dissipated, but its infectiveness is beyond cavil. That it will spread among healthy cattle when they are kept with diseased ones is well known.

Tuberculin Test.—This has been stated by many to be an infallible guide in the diagnosis of bovine tuberculosis. I may say that it depends largely on the infallibility of the man who uses it. If a correct selection of animals is made, leaving out any that should not be tested, and the proper amounts of tuberculin are used for the varying ages and conditions, then if the temperatures are taken without errors, we shall have tables that, if correctly interpreted, are very valuable in determining the number of animals that are free from tuberculosis, and the number that are not. But tuberculin is not an automatic machine; it requires brains, judgment, and experience to make a test and then read the answers correctly. When used with these prerequisites, it is a highly efficient diagnostic agent.

Percentage of Diseased Cattle in Herds.—In some herds of cows of dairy age the percentage may run from twenty to ninety per cent., and now and then a herd may be found in which every animal is infected. In herds in which there is a goodly number of young animals the percentage is smaller. Young animals are comparatively free from it. Mature cows give the largest percentage of victims, those from a year and a half to three years old the next, and those less than a year old the least. There seems to be diversity of opinion among physicians as to whether tuberculosis is more common in adults or children. This point should be settled, and it should be demonstrated how and from what source infants obtain infection. It has been convenient up to this time to attribute thousands of cases to the ingestion of cow’s milk. The Veterinary Journal, London, England, for June, 1889, gives an account of a meeting of the British Medical Association at Glasgow, and Dr. Carpenter stated that eighty per cent. of the cattle sent to the principal meat market in London were affected. Professor McCall said that twenty-five per cent. would be nearer the mark for Glasgow. In Saxony it is said to be about one per cent.; in Berlin, 3.2 per cent. New York State Tuberculosis Committee’s Report for 1895 states that about seven per cent. is figured as the average for the whole State. The writer examined a herd in this State last week in which twenty-seven out of thirty animals were tuberculous, and some were in the last stages of disease. Three youngsters were free from it. Another herd examined in Connecticut gave about fifty per cent. of diseased adults. Nearly half of the healthy ones were under two years old.

Transmission.—We have now arrived at the point upon which hinge very largely the health and welfare of humanity and the fate of millions of dollars’ worth of cattle. Is bovine tuberculosis communicable to the human subject? This is the paramount question, and
it must be intelligently answered. The physician, the biologist, and the veterinarian are called upon to solve this problem, and below we give opinions from each, as well as from the State board of health, using these merely as examples of the universal opinion on the subject. We have noticed that so far as heredity, breed, sanitation, spontaneity, and predisposition are concerned, there has been a vast amount of error taught, we will now consider transmissibility. J. H. Girdner, A. B., M. D., in an article published last month on disease germs and how to avoid some of them, states that "the other principal source of human infection is from drinking the milk and eating the flesh of tuberculous cattle. Tuberculosis in children usually manifests itself in diseases of the bones and joints, white swelling, and in enlargement and suppuration of the glands of the neck. In nearly all such cases the infection comes from drinking milk from tuberculous cows." Bulletin 118, New Jersey Experiment Station, on the suppression and prevention of tuberculosis of cattle and its relation to human consumption, by Jules Nelson, biologist, contains these words: "But it is principally for man's sake that the lower animals should be included in the general scheme for freeing the country from this evil." In the Journal of Comparative Veterinary Medicine, December, 1897, C. C. McLean, veterinary surgeon, and a milk inspector in Pennsylvania, contributes an article which was read before the State Veterinary Medical Society. The following is a part: "The houses of the wealthiest in the world and the homes of the poorest testify that our meat and milk supply cause thousands of deaths from this disease every day. Tuberculosis is therefore the most important disease for the veterinary profession to deal with." The report of the New York State board of health to the legislature of 1895 contains the following: "There is a complete unanimity of opinion now in the scientific world as to the communicability from man to man, and from animal to man, and man to animals. That milk and its products will convey it has been proved repeatedly. This has now passed beyond the experimental stage, and is no longer open to doubt. It has also been proved that lower animals fed with tuberculous meat become tuberculous as a result of such feeding." Such, then, is the common opinion to-day. Many of the statements are couched in language calculated to defy further investigation and to discourage even a doubt as to their correctness; however, we shall endeavor to show by the conditions as they exist between man and animals, and animals and man, that no stress of words, no amount of bigotry, no arbitrary proclamations unsupported, can hold the truth in bondage. If the State board of health believed its own teachings and was sincere, why did it inspect, tuberculin test, condemn, quarantine, and tag for slaughter various lots of cattle which, according to the board's Reports, were inimical to the public health and were prone to spread disease among other cattle, and after holding them in quarantine a considerable time pass a resolution and send out the following notice to the owners of said diseased cattle?

"You are herewith notified that the quarantine imposed upon your cattle by the inspectors of this board, in pursuance of orders from this board, and in conformity with the power granted by article 4 of chapter 661, laws of 1893, is relieved and raised, and the tags and other devices used to mark said animals may be removed by you." As well might our penitentiaries be thrown open and the murderers and convicts be told to go free, and that any striped clothing or other devices used to mark said criminals might be removed by them.

The board of health of Syracuse, New York, has determined that hereafter all the herds whence the milk supply of the city is derived shall be kept under municipal supervision, and that all dairy animals shall be examined by a physician at least twice a year. A round aluminum tag is fastened to the ears of the healthy animals, and an oblong tag to those of the diseased ones. If physicians in State boards of health and in other positions are competent to handle animal diseases, then, to be consistent, we should have a corps of veterinary surgeons to guard the public health. Both are doctors. Could Miles do what Dewey did? Could Dewey win where Miles has won? Both are fighters. While I have the utmost respect for and confidence in the ability of the medical profession, I can but regret that its code of ethics allows its members to imperil its dignity by seeking positions and assuming roles in which they are manifestly out of their proper sphere. To the honor of the profession be it said that its ablest members are not dissemblers, and that only its pygmies pose as veterinarians. But we have digressed from the subject of transmission. We have been told over and over again that the slight difference between the bacillus of man and that of cattle is a temporary peculiarity, and is overcome when the conditions are favorable. . . . That all over the world tuberculosis in man and cattle coexists in the same locality; that among fish eaters and in countries having no cattle tuberculosis is practically unknown. That it prevails largely among beef eaters and cow-milk drinkers; that among our Indians, who eat diseased beef raw, fifty per cent. die of tuberculosis, while among the northern Indians, who never see beef, it is relatively unknown, goes to show that the conditions being favorable the infection passes readily from ox to man." Professor Law used this argument in an article published last month: "I deny that it is shown that the infection passes readily. Coincidence is the only thing established. Conditions that favor the spread of this disease from human to human also contribute to its dissemination from bovine to bovine." Rivers and railways often run side by side for the reason that Nature in such places favors both, and not because there is any relation between them, or that one is necessary to the other. Since we know the cause of
MOORE: BOVINE TUBERCULOSIS IN ITS RELATION TO MAN.

Sept. 2, 1899.

MOORE: And believe am Thus 337 If am those cattle, determined, gave and eases result dence of do kind effecting. tuberculosis them, Sept. 1899.

Albany man, herd many cattle, to the newspapers disease position I have now possiblity that such as tuberculosis, to the owner's advice. The advice given then is equally applicable now—viz., that cattle owners should have their herds inspected; that the diseased ones should be isolated; those that were physically bad should be killed. Disinfection was advised for stables, etc. In 1885, after killing two thousand dollars' worth of cattle in another State with the owner's consent, there being no law to compel slaughter in any State at that time, I gave the Albany Argus a column article on Animal Diseases and their Relation to the Public Health, and on the subject of tuberculosis, said: "How much of the prevalence of human tuberculosis may be due to milk and beef from tuberculous cattle is a question yet to be determined, and is a serious one indeed." Therefore, the position I now take after having warned the public many years ago, and frequently since, to use all possible care to prevent the transmission of tuberculosis from cattle to man, is arrived at from a vast experience with the disease in cattle in England, Canada, and the Eastern and Middle States, and from a study of the people most exposed to any infection that might be possible from such animals.

Bacilli in Human and Bovine.—Charles Darwin says that man has given rise to many races, some of which are so different that they have often been ranked by naturalists as distinct species. The races differ in constitution, in acclimatization, and in liability to certain diseases. On these same principles micro-organisms are very much modified by the conditions surrounding them. Sternberg, in his Manual of Bacteriology, states that the tubercle bacillus is a strict parasite, and its biological characters are such that it could sacrely find natural conditions outside of the bodies of living animals favorable for its multiplication. It therefore does not grow as a saprophyte under ordinary circumstances. But it has been noted by Nocard and Roux that when it has been cultivated for a time in artificial media containing glycerin it may grow in a plain bouillon of veal or chicken, in which media it fails to develop when introduced directly from a culture originating from the body of an infected animal. The human is omnivorouls, the bovine is herbivorouls. The normal human pulse is about 72, that of the ox 40 to 45. The normal temperature of the human is 98.6° F., that of cattle from 100° to 100.5° F. Thus the normal temperature of the ox is equal to quite a fever in the human. I am of the opinion that there is something in the human body antagonistic to the favorable development of the tubercle bacillus of the bovine, and there is in the body of the bovine a check to the colonization of these animals by the bacilli from the human species. Hordes of Hottentots transferred to the polar regions would rapidly perish, yet the Eskimo thrives there. Sternberg says: "A certain species of bacilli may be pathogenic for one species and not for another. Thus the anthrax bacillus, which is fatal to cattle, sheep, rabbits, guinea-pigs, and mice, does not kill white rats. The bacillus of mouse septicemia kills house mice, but field mice are fully immune from its pathogenic effects. On the other hand, the bacillus of glands is fatal to field mice, but not to house mice." Here is a distinction as finely drawn as that which I have alleged as existing between man and the ox. I believe that the tuberele parasite of man has by its long existence in that host acquired, as it were, individual characteristics which unfit it for life in the ox, and that the "micro-organism" of tubercule, which for centuries has had its habitation in cattle, has become practically specific to that class of animals. I am therefore persuaded that if the environment be changed in either direction the pathogenic power will be lost. I have read of cases of accidental inoculation of the human from the bovine, and if they have occurred they must be very rare, inasmuch as none have come under the writer's observation, and probably no one has had greater experience with tuberculosis in cattle. I am positive that many supposed cases have been incorrectly interpreted. Suppose
one member of a family on a farm develops tuberculosis, and there are one or twenty tuberculous cows on said farm, it does not prove that the individual obtained the infection from the bovine. It is quite probable that he has been exposed to infection from human tuberculosis hundreds of times. Many reported cases hang on just such vague evidence as this. If a man walks into a bank, and while there is found to have twenty dollars in his pockets, is it prima facie evidence that he has become infected with the germs of wealth of that institution? Or, is it not possible that he was suffering from monetary engorgement when he entered that hotbed of filthy lucre? It must be proved beyond peradventure that he was penniless when he entered the building if we are to blame the bank for the condition of his pockets. Just as positively must we know that infection passes to the human adult or child from cow’s milk or its products, or from beef, or through ingestion in other ways, or by inhalation of bacilli from the bovine, and that they alone establish the disease ere we can truly say there is such transmission. How may we know that a human being is tuberculous when no germs can be obtained from the subject, and no marked symptoms are observed? If an adult or child has tuberculosis, and it is proved that such patient has partaken of milk for any length of time from a cow known to be tuberculous, it is by no means certain that infection came from the cow unless there is proof that it did not come from the human, and that it did not exist prior to his ingestion of the milk. Let us take cognizance of the difficulty of establishing such a fact. Humanity wanders incessantly. The germs of human tuberculosis are wafted on the winds, are carried by the waters, may be brought home in food or clothing, may be inhaled at church, theatre, or hotel, in motor or parlor cars. They do not stand out in large black masses, like the rocks the mariner is ever alert to avoid, but without our ken, noiseless, imperceptible, and intangible they surround and invade us. They do not sting when they capture a victim; then how can we know the time, the place, and the source of infection? Even the milk from that tuberculous cow just mentioned may be further contaminated by bacilli from a human being before it reaches the consumer, and the bacilli from the human may establish disease, while the bacilli from the cow prove inert. Consumption in people is so common that physicians have unlimited facilities to study its etiology. For instance, in New York State the deaths from this disease for eight years from 1888 to 1895 were 104,804, an average of 13,100 a year, and it averaged about eleven per cent. of all deaths. The annual report of our State board of health for 1896 says: "Tuberculosis in some form or other accounts for a very large percentage of the deaths in the State, and when it is known that there is at the present time a large amount of meat consumed from tuberculous cattle, and that milk from such cattle enters into the dietary of the people, and that there is danger when the bacillus is ingested, it is believed to be a most potent source of infection, especially in children." Note the expression, believed to be, and if we read from scores of writers on this subject, we shall find that when they come to this point they all hide behind just such terms. Where are their facts, and why do they not give us some positive statements, with convincing illustrations of the methods by which they proved to themselves that such was the case? Too long have writers worn the thinking caps of others, too confidently have they accepted the statements of supposed authorities. There has been too much heredity in ideas and quotations. Practically all the people of the State eat the products of cattle all their lives, and tuberculosis in cattle is well distributed throughout the State. Now, then, if the disease passes readily to man, even laymen should be able to note the fact where large numbers of cattle are infected. But they, and their physicians, and their veterinarians have merely presumed, imagined, believed, supposed, and concluded that such “might be the case.” One thing is well known, viz., that 13,000 human consumptives give off enough infective material annually to account for all the human tuberculosis in the State without the aid of a single bovine.

(To be concluded.)

THE THERAPEUTIC VALUE OF OXYGEN.*

By W. L. CONKLIN, M.D.,
ROCHESTER, N. Y.

Of the many problems which confront the physician the one which requires for its solution the determination of the therapeutic value of a drug or remedial agent is by no means the most simple. Indeed, it is a problem so complex and difficult, when viewed from the physiological as well as the clinical standpoint, that we are sometimes tempted to reject a remedy at once rather than undertake to satisfy ourselves as to its real value. Then, too, the number of new remedies to which our attention is called is so great as to make a thorough clinical test of each an impossibility, even if such a test were desirable. There can be no doubt, however, that among the many worthless or unnecessary drugs and remedial agents presented to us there are others of great value. To deny this fact is to deny that any real progress is being made in therapeutics, and this no one of us would be willing to do. The process of sifting out the good from the worthless is constantly going on, but physicians are, as a class, conservative, and slow to place a new candidate for favor on the list of remedies of undisputed value. Opium, quinine, and calomel are there, and seem likely to remain for all time, but there are many other remedies, the therapeutic value of which is still the subject of discussion, which may, in time, come to be re-

* Read before the Rochester Pathological Society, May 18, 1899.
garded quite as worthy as these of a place in the list. We can not afford to discard or set aside without sufficient cause any weapon which promises to be of service in our combat with disease. Neither can we afford to wage a passive warfare. It is an encouraging evidence of progress in our knowledge of therapeutics that less is heard than in former years about the "expectant plan" of treatment. The term implies a graceful recognition of the curative powers of Nature, but does not do full justice to the physician, if it means that with his own experience and that of others to draw from he can find nothing with which to aid Nature in her work. We never hear of the "expectant plan" of dealing with a mad dog, or of the "expectant plan" of saving a drowning child, and it is to be hoped that the time will come when this term shall no longer be found in our medical text-books.

In our efforts to combat disease, however, we often find our therapeutic resources inadequate, or, to put it in simpler language, our patients don't all get well. No doubt this will from the nature of things continue to be the case, but the more scientific our methods, and the more perfect the adaptation of the remedy to the disease, the smaller will be the proportion of failures. Shall we not then seek from time to time to add to our list of remedies and so better our equipment for successful work?

Two considerations have led me to select as my subject The Therapeutic Value of Oxygen: First, a firm conviction that oxygen administered by inhalation is worthy of a place among remedial agents of positive value, and, second, an impression that many physicians hold an opposite view, regarding it of doubtful or very limited utility, and rarely if ever make use of it in their practice.

Hare says: "With regard to the usefulness of oxygen inhalations, there has been and is much dispute among physiologists and clinicians alike. One party denies the possibility of adding to the oxygen of the blood by any such means. Among these are Ewald and Peabody. A second party maintains the exact opposite, its members differing only in the degree of value which they attach to the inhalations. Oune, Hayem, Albrecht, and Durjardin-Beaumetz take this view of the subject. A third party preserves a cautious neutrality, not denying the possibility of usefulness, but holding it to be very doubtful or slight. Nothnagel and Oertel are prominent members of this neutral party. While this difference of opinion obtains regarding the therapeutic value of oxygen inhalations, there can be no diversity of opinion among physicians as to the therapeutic value of pure air and plenty of it. And no doubt it would be hard to improve on Nature's combination of twenty-one parts of oxygen and seventy-nine of nitrogen for the ordinary requirements of life, or for our patients even, providing we can get them into the pure air and then get them to breathe in such a way as to avail themselves of the oxygen which it contains. But there are many pathological conditions in which, for one reason or another, it is impossible to get enough atmospheric air into the lungs to supply the tissues with the oxygen which they need. It is for the relief of these conditions that the inhalation of oxygen, properly diluted, is indicated, and, in my opinion, of very great value.

One of the press dispatches regarding Rudyard Kipling's condition stated that a cylinder of oxygen had been carried to his room, and added that this was regarded as heroic treatment and a "last resort," and it is undoubtedly true that in the minds of many of the laity and some physicians oxygen is limited to this narrow sphere of usefulness. I say narrow, for "last resorts" are usually just what the term implies, and I feel sure that while sometimes of value in these desperate conditions, its utility is by no means limited to them. It is often thought of and sent for in haste when cyanosis is well marked or cardiac failure impending; but if of any value in these urgent conditions, would it not have been of far greater value by preventing the development of these same conditions if resorted to earlier in the course of the disease? It must necessarily often fail to do more than give temporary relief when its use is delayed, and it may be that failure at this time has led to an underestimate by some of its real therapeutic value.

It is true that but little is said in most of our standard text-books in regard to oxygen. It is true, also, that certain laws which govern the diffusion and absorption of gases are sometimes looked upon as interfering with the utilization of oxygen as a therapeutic agent. I hope to show that this is not, in reality, the case, and I feel confident that while little prominence is given to oxygen in most of our text-books, there is no lack of clinical evidence to prove its remedial value. Permit me first to review briefly some of the phenomena of respiration.

Without going into particulars regarding tidal, complemental, reserve and residual air, let us follow a hundred volumes of atmospheric air as it enters the lungs, noting the changes which occur in its composition and in that of the blood with which it comes into contact. Of the one hundred volumes there are approximately seventy-nine of nitrogen and twenty-one of oxygen, with a trace of carbon dioxide and watery vapor. When expired the air has risen in temperature to about 98.5°F., there has been an increase in the amount of watery vapor, traces of organic matter and free ammonia are present, and 4.8 volumes of oxygen have been abstracted, while 4.3 volumes of carbon dioxide have been added.

The interchange of gases which takes place between the inspired air and the venous blood is of vital importance. Dalton says: "The most constant and striking phenomenon presented by living organisms, both animal and vegetable, is the absorption of oxygen. A supply of this substance, either in the gaseous form as a constituent part of the atmospheric air, or dissolved in water or other liquids, is indispensably requisite for the main-
tenance of life and the manifestations of vital phenomena.”

Hare says: “Its proper supply is an indispensable factor in function and in nutrition, and although its action is apparently destructive, it is the chief of constructive agents.”

The importance to man of a full supply of oxygen is shown by the fact that if its proportion in the air breathed is reduced to ten per cent. asphyxia results almost immediately.

The recent investigations of Oehrvall would seem to show that oxygen has a peculiar vitalizing effect upon the heart muscles. He finds that “a volume of blood sufficient to fill the frog’s ventricle will maintain contractions for hours, provided the heart is surrounded with an atmosphere of oxygen. The heart is brought to a standstill by lack of oxygen and may be made to beat again, even after an arrest of twenty minutes, by giving it a fresh supply. The heart fails in oxygen hunger probably because the chemical process by which the stimulus to contraction is called forth no longer takes place.”

It is an interesting and important fact that the law of “partial pressure” which, as a rule, governs the absorption of gas by a liquid, does not apply to the absorption of oxygen by the blood except so far as the fractional amount found in the plasma is concerned. This law is briefly stated as follows: “Other things being equal, the amount of gas which a liquid absorbs depends upon the proportion of gas—the so-called partial pressure of the gas—in the atmosphere to which the liquid is subjected. Conversely, if a liquid containing a gas in solution be exposed to an atmosphere containing less of the gas, the gas will be given up to the atmosphere until its amount in the liquid and in the atmosphere becomes equal. This is called the condition of equal tension.”

The rapid escape of gas when the cork is removed from a bottle of carbonated water is an illustration of this law. The water is charged with carbon dioxide, while the atmosphere contains only one volume in two thousand, and the gas escapes until a condition of “equal tension” results.

Nearly all the oxygen of the blood is found in loose chemical combination with the hemoglobin, and this combination is independent of the law of partial pressure. Pfliiger found 15.6 per cent. by volume of oxygen in the entire blood of the dog, while the serum alone contained only 0.2 per cent.

The oxygen tension of the venous blood, then, depending as it does, upon the amount of this gas which is in solution in the plasma, is low, and this condition favors the transfer of oxygen from the alveolar air to the venous blood, where it enters, for the most part, into loose chemical combination with the hemoglobin. Recent experiments have seemed to prove, however, that the oxygen tension of arterial blood, as it leaves the lungs, exceeds that of the air in the alveoli, and it has been thought by some physiologists that the lungs possess the power of absorbing oxygen. Haldane and Smith (Journal of Physiology) find proof that this theory is correct in the fact that “when the proportion of oxygen in the alveolar air is diminished the relative excess of the oxygen tension in the arterial blood over the alveolar oxygen tension is markedly increased.” The lowering of arterial oxygen tension in diseased conditions, especially those affecting the lungs, is thought by them to afford further proof in favor of the absorption theory.

The affinity of hemoglobin for oxygen is so great that one gramme in solution will absorb 1.59 cubic centimetres of oxygen. This is equal to about ten volumes of oxygen to a hundred of venous blood. The capacity of hemoglobin as an oxygen carrier and the demand of the tissues for this gas is shown by the fact that on the average, in the healthy adult, about sixteen cubic centimetres are removed from the air and absorbed by the blood with each respiration. This would amount to at least a hundred and twenty-five gallons in twenty-four hours.

The venous blood comes to the lungs loaded with carbon dioxide. As this gas is largely in solution in the plasma it passes through the alveolar wall by a process of diffusion and in accordance with the law of partial pressure, the carbon dioxide tension of alveolar air being less than that of venous blood. About eight ounces of carbon are in this way removed from the blood in twenty-four hours.

If, as Dalton says, oxygen “is indispensably requisite for the maintenance of life,” if the reduction of its proportion in the atmosphere to one half the normal amount will produce almost immediate asphyxia, and if the demand of the tissues for it is so great that in health they require at least a hundred and twenty-five gallons in twenty-four hours, then it is evident that if, for any reason, the supply is markedly diminished, or the blood so changed in composition that it is no longer a good oxygen carrier, there must result a condition of oxygen starvation quite as menacing to life as is the starvation resulting from an insufficient supply of food.

It has been well said that “to feed a hypertrophic subject therapeutically by way of the alimentary canal alone is impossible. Attention to respiratory diet is equally necessary.”

This diminished supply must result from any condition which interferes with the function of respiration, either by obstruction to the free ingress of air, or by diminishing the total diffusion area of the alveoli. Such conditions are present, e.g., in the various forms of pneumonia, and in asthma, pulmonary tuberculosis, and membranous laryngitis.

The blood changes which take place in chlorosis, progressive pernicious anemia, and in all the secondary anemias, result in a diminution in the number of red blood-corpuscles and in the amount of oxygen carried
by the blood to the tissues. Indeed, "oxygen hunger" exists, in greater or less degree, whenever dyspnœa is present, and Pepper enumerates fifty-five distinct morbid conditions in which this symptom is prominent.

If, when the supply of oxygen obtained from the atmosphere is insufficient, this insufficient supply can be supplemented by inhalation of the gas, properly diluted, much may be done to relieve the distress resulting from dyspnœa and to bring about a return to perfect health.

This query might be answered in the affirmative at once if the oxygen of the blood were in solution in the plasma and so subject to the law of partial pressure. An increase in the proportion of oxygen in the air inhaled would necessarily be followed by an increase in the amount of oxygen taken up by the plasma. But, as we have seen, this law does not apply to the absorption of oxygen by the blood, and physiologists claim that the amount of oxygen entering into combination with the haemoglobin is not increased to any extent by breathing the pure gas. This may be true when, as in perfect health, the haemoglobin is already saturated with oxygen. It may be true also in diseased conditions in which the blood is deficient in oxygen, for pure oxygen is an irritant to the lungs, and, by reason of its irritating properties, likely to interfere with the delicate physiological process by which diffusion is carried on.

But if the haemoglobin is deficient in oxygen and the resulting oxygen hunger of the tissues well marked, and if oxygen is administered properly diluted with a non-irritating gas, it is undoubtedly taken up by the haemoglobin, and in turn by the tissues, with resulting relief to the distressing and threatening symptoms not only, but with positive benefit to the patient as well.

Kirkes says: "If blood containing little or no oxygen be exposed to a succession of atmospheres containing more and more of that gas, absorption is at first very great, but soon becomes relatively very small, not being therefore regularly in proportion to the increased amount or tension of the oxygen of the atmospheres."

This fact in physiology has an important bearing upon the subject. It would seem to prove conclusively that while increase of tension or partial pressure is not followed by an increase in the amount of oxygen absorbed by the blood, a diminution in the amount of oxygen in the blood and tissues will be followed by an increased absorption, providing an increased supply is furnished in such a form that it can be readily taken up by the haemoglobin. The law of physics which controls the absorption of a gas by a liquid is, then, in perfect accord with the observations of physiologists and with the clinical fact that, other things being equal, the greater the dyspnœa, the more pronounced the deficiency of oxygen in blood and tissues, the more marked and positive is the benefit resulting from the inhalation of oxygen.

I will not weary you with a detailed account of my own experience with oxygen. I have used it in a variety of pathological conditions accompanied by dyspnœa, with uniform relief so far as that distressing symptom was concerned, and with marked benefit to the patient as well, in nearly every case. The cases which I remember as having shown the most pronounced improvement under its use include one of broncho-pneumonia in an infant, one of double lobar pneumonia in a child five years old, one in the advanced stage of chronic valvular disease, and one of neurasthenia with persistent anaemia. The case of broncho-pneumonia was markedly cyanotic and in a semicomatose condition when the administration of oxygen was begun. The case of double pneumonia was a desperate one, but finally made a good recovery. The patient with advanced valvular trouble suffered from orthopnoea and great restlessness for weeks, but would often go to sleep sitting in her chair while inhaling the oxygen. The relief of dyspnœa in this case was very pronounced. The anaemic patient was greatly benefited by oxygen inhalations combined with iron, though the iron alone had seemed to afford but little relief.

I have always used the mixture prepared by the Walton Oxygen Works and kept constantly in stock by the Paine Drug Company. This is made according to the formula of the London Oxygen Hospital and consists of one part of oxygen and two of nitrogen non-oxide. The latter gas has anesthetic properties which make it of value, and the mixture is not irritating to the lung tissue, as pure oxygen is said to be.

In looking over current medical literature I find many cases reported in which the results obtained from oxygen inhalations are so evidently favorable as to furnish, it seems to me, strong clinical proof of its therapeutic value.

Believing, as I do, that there are no facts in physiology or in physiological chemistry which really discredit this clinical evidence, or prove that the use of oxygen is unscientific, I feel confident that it will steadily grow in favor and come in time to be considered of definite and positive therapeutic value by all who will give it a fair trial.

232 South Avenue.

CEREBRAL AND MENINGEAL SYPHILIS TREATED BY INTRAMUSCULAR INJECTIONS OF INSOLUBLE SALTS OF MERCURY.

SOME POINTS IN TECHNIQUE.

By J. COPLIN STINSON, M.D.,
SAN FRANCISCO.

The following case of brain syphilis is reported as illustrating the immense value of intramuscular injections of insoluble salts of mercury:

CASE I.—M. G., aged fifty years, contracted syphilis in 1876. For a month after infection he took medicine
from some friends. Then he consulted Dr. Van Vlach, who prescribed medicines that were taken three times a day continuously for six months. In June, 1877, he went to Walton Springs in San Benito County, California, where he remained three months. He became fat, strong, and healthy again after this course of treatment. He has always taken good care of himself and he remained well up to the spring of 1897, when he gradually began to lose his health. He complained of vertigo, and sometimes of nausea and vomiting; later on of headaches, which gradually became severe and persistent. The pain was most severe at the front and top of the head, which felt as though some one was beating it with a hammer. He also had pain in the temporal and frontal regions. The muscles of the back of the neck were painful, felt twisted into a knot, and it hurt him to attempt to extend his head. He has been so miserable that he could not work for this last couple of years. From the beginning of April, 1899, his symptoms were much worse, nausea, vomiting (he would eject milk and almonds after), and right of members nearly all the time. He would have deafness and ringing in his ears before the aching commenced. His skull was tender to the touch; sight poor, double vision, read a paper with much difficulty; no position would relieve the pain in the head; the eyes had a peculiar vacant expression; several times he had a numb feeling in his arms, as though paralysis was pending. It was with much difficulty he could walk across a room—frequently he would stagger on account of the unsteadiness of his limbs. For these reasons he could not follow his trade, that of a house painter. For two weeks he could not sleep night or day on account of the severity of the pains in his head. In the latter part of April, 1899, he was found several times wandering around the halls of his lodging house in an exhausted condition, undressed, and acting as though he had lost his reason. On April 28th he was given a large sleeping powder, and about an hour after he was found wandering in the halls. He was taken to his room and while he rested on the edge of his bed he fell over unconscious. A physician was called in, examined him, and stated that he would probably die before morning. He remained unconscious fourteen hours. I saw him on April 29, 1899. He was in a weak, exhausted condition, sight dim, diplopia; felt weak in the legs; patellar tendon reflexes were normal; he could not walk a straight line nor stand steadily with the eyelids closed. He complained of pain, etc., in his head, as already described. He weighed less than a hundred pounds, whereas his weight in robust health had been a hundred and forty-eight pounds. I gave him an intramuscular injection of the salicylate of mercury, two grains, suspended in about half a dram of sterilized almond oil. The injection was made with a needle two inches long and introduced into the muscular tissues of the buttock about a quarter of an inch above the junction of middle and inner thirds of a line extending from the top of the great trochanter of the femur to the crest of the buttock, meeting the latter at right angles. I ordered some powders to produce sleep and tonic pills to overcome his anaemia. The injection acted like magic; the pains in his head and neck rapidly disappeared, and inside of four days the soreness and tenderness of his skull had also gone. Within a week he went to work at painting for a day and a half, and within three weeks he could work steadily, although it exhausted him. On May 5th I gave him the second injection into the other buttock. The dizziness disappeared, and the stomach was normal after this injection. By June 20th he had been given nine injections. After the fourth injection he weighed a hundred and twenty-five pounds. By June 12th he could walk a straight line fairly well, and work on high buildings. By the latter part of June his sight was better than it had been for ten years. In the first week of July he weighed a hundred and twenty-nine pounds, the weakness in his knees had nearly all disappeared, and he could work all day with only slight exhaustion. As a rule he did not have any severe pains from the injections. The day following and for a few succeeding days he would have some pains in the buttock, etc., like mild rheumatism. At the sixth injection I used one grain of subchloride of mercury. It was very painful the following day and the pain continued for about two weeks. After the first injection of the salicylate the bowels moved twelve times in forty-eight hours, but during the whole course of treatment they moved on an average about twice a day. After the fifth injection the gums became slightly tender. After the fifth injection the gums became quite tender and sore. After the ninth injection several teeth became loose and the submaxillary glands perceptibly swollen. With mouth washes the swelling subsided within a week, and by July 14th his mouth and teeth felt about all right. On June 24th, on account of the salivation, etc., I discontinued the injections and ordered ten minims of a saturated solution of iodide of potassium three times a day in soda water, increasing two drops daily. When he got up to twenty-two minims for a dose he began to have coryza and a few other symptoms of the iodism, and was put back to ten minims for a dose, which he continued to take till the next series of injections. His general health and condition are now good, and his improvement is such that he will soon regain his former good health.

Points in Technique, etc.—In tertiary syphilis, as in other stages, a thorough course of treatment should be followed if one wishes to cure. Four series of injections should be given each year for three years or longer. If the salicylate of mercury is used and two grains can be tolerated at each injection, two injections should be given a week, and this treatment continued for about five weeks—i.e., till nine or ten injections are given. Forty per cent. of patients take two grains without any inconvenience. Forty per cent. more can not stand two grains, as it produces too many movements of the bowels, quite painful colic, sometimes considerable pain in and around the region of the buttock, and exceptionally a few bloody stools. These patients can be given with little discomfort about a grain and a third of the salicylate at an injection, which is therefore given three times a week; while the remaining, about twenty per cent.—hyperæsthetic individuals—will not take intramuscular injections of two grains, as they cause pains and lameness, on account of which they will not submit to them. Between the series of injections ten minims of saturated solution of iodide of potassium in water should be given three times daily. If there are urgent symptoms, increase two minims daily until coryza and a few other symptoms of iodism appear, when the original dose may be resumed.
Mercury is the curative drug for syphilis, while the iodide is used as a prophylactic against syphilitic endarteritis.

The technique of the injections is simple and safe.

1. Sterilize by boiling four ounces of oil of sweet almonds, which is kept in a sealed sterilized bottle. 2. Use pure salicylate of mercury that has been put up in a sealed half-ounce bottle and prepared by some reliable firm — e. g., Merck. 3. Weigh out accurately the amount to be used for one injection on a clean paper. 4. Put the powder in an aseptic small mortar and pour in about half a drachm of the sterilized oil; triturate well. 5. Place the patient flat on his stomach, legs extended; disinfect area of injection with 1-to-500 bichloride-of-mercury solution. 6. Sterilize the needle (two inches long) by syringing with alcohol and bichloride solutions or by boiling or some other method. If bichloride is used, wipe the needle off at once with dry cotton, which removes the bichloride, prevents tarnishing, and, in fact, makes the surface of the needle shine better than before. The syringe I employ is one used ordinarily for aspirating (five inches and a quarter long, three quarters of an inch wide), with a thumb and two finger rings at the end of the piston, which thus readily forces the fluid along the needle into the tissues. 7. Draw the fluid into the syringe, stirring while doing so with the end of the syringe; fit or screw on the needle and force the fluid along the needle till it appears at the point, which is wiped dry with cotton. 8. Plunge the needle vertically into the tissues the full two inches of the needle, introducing the point about a quarter to half an inch above the junction of the inner and middle thirds of a line carried from the upper border of the great trochanter to the cleft of the buttock at right angles. 9. Inject the oil slowly, and when the syringe is empty withdraw the needle slowly. This prevents any of the fluid being deposited in the fatty tissues, which is a source of some pain. Dust on a little arsitol or other mild antiseptic and pour on a few drops of collodium, which is allowed to dry. I have often used and have frequently seen intramuscular injections of the salicylate of mercury used, in the treatment of syphilis, and have yet to see the first case wherein an abscess formed. Forty per cent. with two grains and forty per cent. with a grain and a third have little or no pain with or after injection, and no rest is required. In all cases the absorption of mercury was definite in amount and its action did not vary much; as a rule, there were no pathological changes produced in the structures injected, and no sudden or dangerous poisoning. Absorption of mercury begins very soon after the injection, as shown by the symptoms and by testing the urine for mercury, which does not disappear from this excretion for four to seven days if two grains have been injected. Subsequent doses are repeated about twice a week so as to obtain a thorough systemic effect. By this means mercury is continuously in the system.

By using injections the functions of the digestive tract, the skin and liver, etc., are not interfered with. The doses are certain of absorption and can be readily regulated according to the susceptibility of the individual; with aseptic and antiseptic precautions the treatment is perfectly safe and the resulting improvement is certain and rapid. Under ordinary conditions the practice is not necessary, and should be condemned, of adding morphine or cocaine or both to an injection. In cases of syphilis with dyspnoea cocaine can be added with advantage, as it rapidly overcomes this distressed condition. I know of a case with marked dyspnoea (cardiac) (in the practice of my colleague Dr. G. Gross), in which cocaine was added to an injection. The dyspnoea ceased immediately, and it was not necessary to repeat the cocaine subsequently.

It is of vast importance before beginning intramuscular injections to ascertain that the teeth are in excellent condition and that the kidneys are not diseased. Patients with nephritis should not receive large doses of mercury by injection, as even small doses are not well tolerated. In all cases the urine should be examined once in a while during the course of treatment.

326 Kearny Street.

A CASE OF COLOCYNTH POISONING.

By WILLIAM ELLERY JENNINGS, M.D., BROOKLYN.

The patient, Mrs. B., aged twenty-nine years, native born, mother of two children, first came under our care on May 28, 1899.

She gave a history of having swallowed, at 8 A.M. on the same day, an improvised tincture of colocynth, prepared by macerating an entire colocynth "apple" in four ounces of gin for twelve hours, with a view to bringing on an abortion.

Symptoms appeared within an hour after the exhibition of the drug in the form of faintness, giddiness, vomiting, and retching, accompanied by considerable pain in the epigastric region. About 11 A.M. patient had a large watery, blood-tinged stool, and shortly afterward a convolution.

I was called to see the case at 2 P.M. Examination showed a normal temperature; coated tongue; pulse of 62; weak and irregular; pulse-respiration ratio much disturbed, and diminished intensity of the first sound of the heart.

Subjectively there was a feeling of extreme prostration, distressing thirst, and severe epigastric pain. Vomiting, preceded and followed by retching, was occurring at about ten-minute intervals. Toward evening a mild delirium set in, and patient was delirious at intervals throughout the night.

During the first twenty-four hours emesis occurred some twenty or thirty times (estimated), with two convulsions and four blood-stained stools.

The following day there were ten evacuations of the bowels, with a continuance of epigastric pain, pulse of 69, and some improvement in gastric irritability, emesis occurring but three times. Prostration still marked.

On the third day there were fourteen stools, and the pulse was 78, with a slight improvement in the general
Therapeutic Notes.

For Nephritis.—The Gazette degli ospedali e delle cliniche for August 1st says that Professor Baccelli, when it is desired to induce energetic intestinal derivation in nephritis, recommends the following formula:

\[
\begin{align*}
R & \quad \text{Sulphate of sodium} \quad 600 \text{ grains;} \\
N & \quad \text{Nitrate of sodium} \quad 300 \text{ "} \\
S & \quad \text{Scammony} \quad 90 \text{ "}
\end{align*}
\]

M. Divide into forty powders. One to be taken every half hour.

Sea Water as a Remedy for Seasickness.—Dr. L. C. Washburn (Merck's Archives, August) says that in addition to a light diet and a mild purge before entering on a voyage, and loose clothing and a recumbent posture in the open air on board ship, the remedy that he has never known to fail is to drink a pint of sea water. This generally produces vomiting, and often acts as a saline aperient, giving prompt relief with no unpleasant sequence.

A Teething Syrup.—The Revue de médecine for July 26th quotes the following from the Gazette des hôpitaux of unnamed date:

\[
\begin{align*}
R & \quad \text{Citric acid} \quad 7\frac{1}{4} \text{ grains;} \\
D & \quad \text{Distilled water} \quad 7\frac{3}{4} \text{ "} \\
H & \quad \text{Hydrochloride of cocaine} \quad 1\frac{1}{4} \text{ grain;} \\
S & \quad \text{Syrup} \quad 2\frac{2}{3} \text{ drachms;} \\
Y & \quad \text{Syrop of saffron} \quad 2\frac{1}{4} \text{ "} \\
V & \quad \text{Tincture of vanilla} \quad 12 \text{ drops.}
\end{align*}
\]

M.

To be rubbed on the gums.

Trinitrine for Abdominal Pulsations.—The Gazette hebdomadaire de médecine et de chirurgie for August 6th, citing the Semaine médicale, says that in the foreible abdominal pulsations coming from the aorta and causing a very distressing sensation, common in nervous subjects and hysteric and neurasthenic women, Sir Wilmoughby Wade finds the best remedy to be trinitrine administered at bedtime in a dose of three decimilligrams (about one two-hundredth of a grain).

A Mixture for Preventing Abortion.—Bossi, of Genoa, recommends the following mixture:

\[
\begin{align*}
R & \quad \text{Fluid extract of hydrastis;} \\
H & \quad \text{Fluid extract of hamamelis;} \\
V & \quad \text{Fluid extract of viburnum prunifolium;} \\
I & \quad \text{Tincture of piscidia;} \\
L & \quad \text{Laudanum} \quad 2 \text{ "}
\end{align*}
\]

M. S.: Ninety drops, in half a glass of water, three times a day.

An Effervescent Preparation of Quinine.—The Centralblatt für die gesammte Therapie for August credits the following formula to the Annales de médecine et de chirurgie:

\[
\begin{align*}
R & \quad \text{Quinine sulphate} \quad 4 \text{ parts;} \\
C & \quad \text{Citric acid} \quad 10 \text{ "} \\
S & \quad \text{Syrup;} \\
O & \quad \text{Syrup of orange peel;} \\
D & \quad \text{Distilled water;} \\
M & \quad \text{S: Ten drops to be taken in two ounces of water in which thirty grains of sodium bicarbonate have been dissolved. The bitter taste of the quinine is said to be overcome.}
\end{align*}
\]

A Saponaceous Dentifrice for the Prevention of Mercurial Stomatitis.—Lanz, cited in the Presse médicale for July 22d, recommends the following:

\[
\begin{align*}
R & \quad \text{Potassium chlorate} \quad 300 \text{ grains;} \\
M & \quad \text{Medicinal soap} \quad 150 \text{ "} \\
E & \quad \text{Calcium carbonate (chalk?)} \quad 300 \text{ "} \\
C & \quad \text{Oil of peppermint} \quad 15 \text{ drops;} \\
O & \quad \text{Oil of cloves} \quad 4 \text{ "} \\
G & \quad \text{Glycerin} \quad \text{a sufficiency.}
\end{align*}
\]

M. Make into a paste.

Besides the use of this dentifrice, the mouth should be rinsed frequently with some antiseptic solution.
SANARELLI'S YELLOW-FEVER BACILLUS.

Recently two notable American contributions have been made to the literature of the controversy that has arisen as to whether or not Professor Sanarelli is correct in concluding that his *Bacillus icteroides* is the cause of yellow fever. One of them, by the Surgeon-General of the army, appeared in the *Medical News* for August 19th; the other is the official abstract of the report of a commission of the Marine-Hospital Service which we published last week. The report was dated July 10th, and of course was prepared before Surgeon-General Sternberg's article came out. The commission consisted of Surgeon Eugene Wasdin and Passed Assistant Surgeon H. D. Geddings, and their investigations were conducted mainly in Havana. Their report, it will be remembered, favors Professor Sanarelli's main contention, although it tends to disprove his theory of the cause of the "secondary paroxysm" of the disease. It traverses the idea, imputed to General Sternberg, that the germ of yellow fever is to be looked for in the alimentary canal; but General Sternberg declares, in the article referred to, that such imputation is erroneous, and adds that he has previously repudiated the notion attributed to him.

General Sternberg's article foreshadows the report of Dr. Reed and Dr. Carroll, whose investigations have been conducted in the laboratory of the Army Medical Museum. The surgeon-general sets forth that Reed and Carroll's experiments do not show that Sanarelli's *Bacillus icteroides* is the cause of yellow fever, but, on the other hand, he admits that Sanarelli's observations do not show that the bacillus X of Sternberg is the germ of the disease, and he declares most unequivocally that so soon as he can look upon Sanarelli's contention as proved he will frankly acknowledge the fact and hasten to do honor to the Italian investigator. "Truth is mighty," he says, "and no doubt in the end will prevail." Both documents are, indeed, pervaded by evidence of the sole purpose of their authors having been to arrive at the truth, and they are singularly free from tokens of prejudice or any disposition to twist facts. Of course, one or the other conclusion must be wrong; either Sanarelli's bacillus is the cause of yellow fever or it is not. The fact that General Sternberg still holds to an opinion absolutely the reverse of that arrived at by the Marine-Hospital Service's commission, we presume, to be imputed to the difficulties and uncertainties still incident to investigations of the kind now under consideration, but it is not easy to account for the diversity of the results observed by the two investigating bodies after feeding pigs with the Sanarelli organism—the surgeon-general of the army has found that pigs so fed fall victims to hog cholera, but the Marine-Hospital Service's commission finds the Sanarelli bacillus innocuous to pigs fed with it. Any attempt to account for this diversity of experience would be pure speculation, and from that we must desist; the matter will be cleared up sometime. Meanwhile we may take heart from the Marine-Hospital Service commission's conviction that a curative serum more potent than Sanarelli's may be produced and that the disease may be rendered far easier of prevention and cure than it has hitherto been found.

THE CRUSADE AGAINST "SWEATING."

We have always been opposed to undue restrictive legislation on any subject, believing that the evil of interference with individual liberty is apt to become a remedy worse in its effect on the community than the evil it is designed to remedy, as it is most assuredly a violation of one of the cardinal principles for which the founders of this republic fought. One might as well be subject to a foreign yoke as to the tyranny of a bare majority of one's fellow citizens, whose ideas as to what is for "the public good" are not necessarily really better than ours because they happen to be held by more people, many of whom simply follow the lead of "crowd suggestion."

It is, therefore, in our opinion a subject for congratulation when there is a prospect of effecting public changes of importance to the community by means of any concerted and organized voluntary action, without recourse to legislation. Such an action we conceive that of the National Consumers' League to be. This society, organized last May, has, so we learn from the *New York Times* for August 28th, achieved a result which it is to be hoped will succeed in bringing pressure to bear upon the labor-sweating firms through the most effective means possible—viz., their interests. It is obvious that if means can be found to interest a majority of the public in the purchase of products guaranteed not to be the result of sweat-shop labor, then those firms that place themselves under contract with the
National Consumers' League will make competition harder for the rest.

The National Consumers' League has, we learn from the *Times*, already signed contracts with a large number of manufacturers of "women's white goods." These contract firms will display and affix to their goods from the 1st of September the label of the league, which label will be a guarantee of the four following points: 1. That all goods are made on the premises. 2. That all requirements of the State factory laws are complied with by the firms using the label. 3. That no overtime work is exacted. 4. That children under sixteen years of age have not been employed. These are surely all points the attainment of which is eminently desirable in the interests both of social economics and of public health.

For the success of such a scheme it is obvious that benefits must be shown to accrue from it to both the manufacturers and dealers on the one hand, and the individual purchasers on the other. Provided that the latter can be awakened to the advantages they derive, the former will inevitably reap their reward in the diversion of the stream of competition in their favor as against other firms which do not follow the same course. It is this difficulty of bringing home to the individual the propriety of putting abstract considerations of the public welfare before, or at least on a par with, his own personal convenience or gain, that is the chief obstacle in any movement of this kind. The person who wants to buy a thing will go where he or she can get the article, considerations of quality, etc., being equal, for the least expenditure. It will remain for the National Consumers' League to convince the manufacturers and dealers that by manufacturing and selling only goods that bear the league's label, they will secure a vantage ground against their competitors who do not so restrict themselves. From the *Times' report it would seem that they have so far had considerable success in their efforts, for we are informed that "instead of being in a position where it was compelled to urge manufacturers to use the label, the National Consumers' League found a willingness on the part of the manufacturers not only to use the label on their goods, but to pay the cost of printing it, and also to protect it at law in case of any infringement." This is very encouraging, and we hope that the manufacturers who fall in with this public-spirited cause will reap their reward in increased trade and public support.

In clothing especially it is a well-known fact that the system of "sweating" by putting out goods to home work is responsible for the dissemination of much infectious disease. In this respect alone, if the National Consumers' League can enforce by "moral suasion" manufacture on the premises and the periodical health inspection of the work people, it will achieve a great public work and one directly affecting the individual purchaser, and will doubtless materially aid the sanitary authorities in checking the dissemination of disease germs. It is too much to hope, we fear, that any measures can be taken to prevent work people, themselves healthy, from carrying disease from homes where infectious disease exists; but something even in that direction might be accomplished by a routine disinfection of all employees on coming to work, thus minimizing the danger as much as possible.

We gather that the "white-goods" trade is simply a beginning, but an appropriate one, for it will appeal directly to women, whose sympathetic tendencies are on the whole more active than those of the male sex. It is expected, however, to extend the operations of the league in course of time, and to carry on an active national crusade.

We cordially wish the National Consumers' League all success in the attainment of its undoubtedly excellent objects, and shall watch the result of its experiment with sympathetic interest.

THE LIQUOR AMNII AND THE FETAL KIDNEYS.

It has long been a matter of discussion as to whether or not the kidneys of the foetus were functionally active, and, consequently, as to whether or not the liquor amnii consisted in great part of the urine of the foetus. To settle the question, Schaller (Archiv für Gynäkologie, lvi, 3; *Deutsche Medicin-Zeitung*, April 24th) has resorted to a most ingenious method of investigation, namely, that of administering phlorrhizin to pregnant women. Phlorrhizin, a constituent of the root bark of various fruit trees, has been known for years to have the property of causing glycosuria when ingested. Schaller's plan was to ascertain if the liquor amnii contained sugar in considerable amount after the administration of phlorrhizin to the mother. If he found none, he would conclude that the *fetus in utero* did not urinate; if he found only a small amount, he would infer that the functional activity of the fetal kidneys was displayed only during the late period of intra-uterine life; if he found it in abundance, he would agree with Gusserow and his followers that the liquor amnii was largely composed of fetal urine. All this was founded on the assumption that phlorrhizin administered to the mother would pass into the fetal circulation and be
carried to the fetal kidneys, and it is in the kidneys that the sugar of phlorrhizin glycosuria is wholly or for the most part formed.

Schaller concludes that there are no regular secretion and periodical excretion of urine by the fetus, even at the very end of pregnancy; that the functional activity of the fetal kidneys does not begin until the process of parturition induces changes in the placental circulation, and that even during labor the fetus does not generally urinate into the liquor amnii; that it is only very exceptionally that the fetal bladder is emptied into the liquor amnii, and then most probably in consequence of disturbances of the fetal circulation; that the liquor amnii is a transudation from the maternal vessels; and that the kidneys of the newborn child perform their function more slowly than those of the adult. These observations seem to settle the question of the relationship of the liquor amnii to the urine of the fetus.

A SPECIAL SYNDROME OBSERVED AT THE ONSET OF CHRONIC PULMONARY TUBERCULOSIS.

M. Fernet (Journal des praticiens, August 5th) described at a recent meeting of the Société médicale des hôpitaux a combination of signs generally found in the initial stage of pulmonary tuberculosis which appears to be of great diagnostic value. In addition to the changes in the respiratory murmur, and the dullness and resistance on percussion found at the apex of the lung, which signs are only suggestive when accompanied by other signs and symptoms, M. Fernet finds very generally the presence of three others: 1. Tracheobronchial adenopathy, which is evidenced by dullness and resistance on percussion found in the interscapular region corresponding to the diseased apex, combined with hollow, quasi-cavernous breath sounds, the expiratory sound being specially marked. 2. Axillary adenopathy on the affected side. 3. A focus of pulmonary engorgement at the base of the affected lung characterized by deadened note on percussion and often by subcrepitant râles. These phenomena collectively constitute links of a chain of symptoms arising from apical tuberculosis. The value of this "syndrome" in establishing the more than ever necessary early diagnosis of phthisis, if fully substantiated, will prove of inestimable value in the prevention and cure of tuberculosis of the lungs.

THE VALUE OF COEDUCATION OF THE SEXES.

Progrès médical for August 5th quotes from the Temps a report of a visit to the "Refuge" of Dr. Stephenson in London for depraved children of both sexes. The visitors, who were delegates from France to a congress for the suppression of traffic in white slaves, say that coeducation gave such marvelous results that, according to Dr. Stephenson, only about two per cent. of the children trained there have returned to their former mode of life. The delegates say that the frank and loyal air, the easy good humor, and the gaiety of the children reared in this establishment were such that they could not at first credit that they were former "incorrigibles," and thought that the children of well-to-do people in the West End of London must have been pressed into service to impress the visitors. Coeducation is a novelty in England, though we have for some time been familiar with its good results in this country. But the test furnished to our French colleagues must be considered a very searching one.

CARBUNCLE OF THE BACK OF THE NECK.

INTERSTITIAL injections of germicides in cases of anthrax of the nucha are no novelty, but their efficacy in an affection which is sometimes very grave deserves to be mentioned from time to time. At a recent meeting of the National Society of Medicine of Lyons (Lyon médical, July 23d) a case reported in which there had been signs of septicemia, the patient being mildly delirious and having a temperature of 104° F. A one-per-cent. solution of iodine, made with the aid of potassium iodide, was injected at five different points, and the injections were repeated in three days. The patient recovered.

THE DEATH-DEALING EXPLOSIVES OF THE FOURTH OF JULY.

We have some excellent laws intended to restrain the prevalent demoniac way of celebrating the Fourth of July, and we are accustomed to annual announcements by the police that those laws are to be enforced, but they never are. We hope, however, that some good may come of the discussion of the subject that was introduced by Dr. William J. Todd at a recent meeting of the Baltimore County Medical Association (Maryland Medical Journal, August 5th). The State's attorney was present and encouraged the association to make its views known to the community.

PROLAPSE OF AN OVARIAN TUMOR WITH THE RECTUM.

The escape of the ovary from the pelvis is not an occurrence of great rarity, but it is uncommon enough to make most instances worth recording. This is particularly true of such a case as was reported lately before the Illinois State Medical Society by Dr. J. A. Baughman, of Neoga (Illinois Medical Journal, August). There was a large prolapse of the rectum, and the right ovary, degenerated and enlarged by a small cyst, was contained in the anterior pouch. The left ovary also was diseased, and both were removed by abdominal section. The woman had passed the menopause.

COMPULSORY REPORTING OF TUBERCULOUS DISEASE.

Ever since some of the health boards began to insist that physicians should report their cases of tuberculous disease there has been, besides resentment on the part of practitioners, the feeling that, on the whole, such reports would do more harm than good, unless great tact was employed. This feeling was well expressed by Dr. J. J. Mulheron in a recent case in which Dr. E. L. Shurly, of Detroit, the well-known laryngologist, was prosecuted for failing to report a case. According to the Detroit Free Press, Dr. Mulheron said: "This measure will frighten people so that relatives of consum-
RAILWAY ACCIDENTS IN THE UNITED STATES.

It appears from the Inter-State Commerce Commission's 'Statistics of Railways in the United States for the year 1898, recently issued in an incomplete form' (without the six statistical tables), that more persons were killed or injured by railway accidents in that year than in any other since 1893. But this was not true of passengers; the increase of casualties was among employees, and no doubt it was occasioned by the necessity of employing many inexperienced men, owing to the great increment of traffic, as is suggested by the statistician, Mr. Henry C. Adams. On the whole, railway travel in this country, we are happy to say, seems to be growing safer every year.

WOMEN NURSES IN THE PHILIPPINES.

It is reported that the medical officers on duty in the Philippines are desirous of having a much larger number of trained women nurses for duty in the military hospitals there than General Otis thinks necessary. It is understood that the surgeon-general has full power and discretion in the matter, and we are confident that he will not turn a deaf ear to such experienced and conservative officers of the medical corps as Colonel Woodhull, for example.

THE OVA OF THE TAPEWORM AS A CAUSE OF PERITONEAL PSEUDOTUBERCULOSIS.

At a recent meeting of the Berlin Freie Vereinigung der Chirurgen (Centralblatt für Chirurgie, August 5th) Helbing reported a case of perytrophilitic abscess, apparently tuberculous, which contained nodules in which, on close examination, the ova of a taenia were detected. It is not stated whether or not there was perforation of the verminiform appendix.

THE PAIN OF PERITONITIS.

H. Nothnagel ('Prager medicinische Wochen-schrift, 1899, No. 14; Centralblatt für Chirurgie, August 5th') properly cautions the practitioner against undue reliance on the stock statement that the pain of peritonitis is never paroxysmal. Sometimes there are distinct remissions. In many respects the teachings of the schools have to be unlearned in the school of practice.

ADHESION OF THE PLACENTA TO THE FETAL HEAD.

This abnormity is among the greatest of obstetrical rarities; apparently there are but two cases on record. The most marked of the two was lately reported in a Croatian journal by von Zderas, and an abstract of his account is to be found in the Centralblatt für Gynäkologie for August 5th. The feto was extracted dead in the fifth or sixth month.

A SURGICAL OPERATION UNDER LYNCH LAW.

The newspapers have recently had accounts of the proceedings of a mob in Falls City, Nebraska, in the case of a man who was in jail under the charge of having indecently assaulted a little child. The man was brought out and submitted to a surgical operation—castration, we presume—at the hands of medical men who had come prepared to perform it. We have nothing to say on the subject of mob punishment in general, because it is beyond the scope of this journal, but we must express our regret that the surgical art should be a weapon in the hands of a mob.

ITEMS.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, cholera, and plague were reported to the surgeon-general during the week ending August 25, 1899:

<table>

Notice to Candidates for Appointment in the Marine-Hospital Service.—The surgeon-general has issued the following notice: A board of officers will be convened at the Service Building, 37th Washington Street, New York city, Wednesday, October 4, 1899, for the purpose of examining candidates for admission to the grade of assistant surgeon in the United States Marine-Hospital Service. Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college, and must furnish testimonials from responsible persons as to character. The following is the usual order of the examination: 1. Physical. 2. Written. 3. Oral. 4. Clinical. In addition to the physical examination candidates are required to certify that they believe themselves free from any ailment which would
Change of Address.—Dr. Bernard Sour, to No. 68 West Ninety-seventh Street, New York.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 19 to August 26, 1899:

Bailey, Guy G., Acting Assistant Surgeon, United States Army, will report to the commanding officer of the United States troops on the transport St. Paul for duty during the voyage to Seattle, Washington, and return by rail to the Presidio, San Francisco.

Bell, Joseph L., Acting Assistant Surgeon, United States Army, is relieved on account of sickness.

Bradley, Henry H., Acting Assistant Surgeon, United States Army, is assigned to duty at the United States General Hospital, the Presidio, San Francisco.

Calkins, George H., Acting Assistant Surgeon, United States Army, will report to the commanding officer of the United States troops on the transport Siam for duty during the voyage to the Philippine Islands.

Cardwell, Herbert W., Major and Chief Surgeon, United States Volunteers, will report on board the transport Senator for duty during the voyage to the Philippine Islands.

Edie, Guy L., Major and Brigade Surgeon, United States Volunteers, will report to the provost marshal general, Manila, for duty with the board of health of that city.

Fowler, E. W., Acting Assistant Surgeon, United States Army, will report to the commanding general, Division of Cuba, for duty.

Gardner, Edwin F., Major and Surgeon, United States Army, is detailed as an additional member of the general court martial convened at Fort Grant, Arizona.

Howard, Deane C., Captain and Assistant Surgeon, United States Army, is detailed as a member of the board of officers to meet at West Point, New York, for the physical examination of candidates for admission to the United States Military Academy, via Bagill, Dallas, Colonel and Assistant Surgeon-General, United States Army, relieved.

Knueppler, William L., Captain and Assistant Surgeon, United States Army, will report to Arthur, William H., Major and Surgeon, United States Army, commanding officer of the United States hospital ship Missouri, for duty.

Swiff, Eugene L., Captain and Assistant Surgeon, United States Army, will report to the commanding officer of the United States troops on the transport Morgan City for duty during the voyage to the Philippine Islands.

Tukey, William H., Acting Assistant Surgeon, United States Army, is detailed on temporary duty at the Presidio, San Francisco, in connection with the medical examination of officers and enlisted men of volunteer troops returning from the Philippine Islands.

Wilson, James S., First Lieutenant and Assistant Surgeon, United States Army, will report to the Department of the Pacific and the Eighth Army Corps for duty.

The following changes in the stations and duties of officers of the Medical Department are ordered: Munson, Edward L., Captain and Assistant Surgeon, United States Army, to Washington Barracks, D.C.; Kemp, Franklin M., First Lieutenant and Assistant Surgeon, United States Army, to West Point; and Gibson, Robert J., Major and Surgeon, United States Army, to San Francisco.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Two Weeks ending August 24, 1899:

Irwin, Fairfax, Surgeon. To proceed to Marseilles, France, and Lisbon and Oporto, Portugal, for special temporary duty.

Wasson, Eugene, Surgeon. To report at Washington, D.C., for special temporary duty.

Geddings, H. D., Passed Assistant Surgeon. To proceed to New York for special temporary duty.

Smith, A. C., Passed Assistant Surgeon. To proceed to Hampton, Virginia, and report to Surgeon J. H. White for special temporary duty.

Stimpson, W. G., Passed Assistant Surgeon. To report at Washington, D.C., for special temporary duty.

Richardson, T. F., Assistant Surgeon. Detailed as quarantine officer for the port of Nuevitas, Cuba.

Richardson, S. W., Hospital Steward. To proceed to Birmingham, Alabama, for special temporary duty.
Peck, F. H., Hospital Steward. To proceed to Hampton, Virginia, and report to Surgeon J. H. White for special temporary duty.

Carmichael, D. A., Surgeon. Granted leave of absence for thirty days.

Wasdin, Eugene, Surgeon. To proceed to Marshall, Virginia, on special temporary duty. Detailed as delegate to the International Medical Congress to meet at Brussels, Belgium, September 4, 1899.

Pettus, W. J., Surgeon. Granted leave of absence for one day.

Stimpson, W. G., Passed Assistant Surgeon. Granted leave of absence for thirty days from August 19, 1899.

Oakley, J. H., Passed Assistant Surgeon. To proceed to Paducah, Kentucky, on special temporary duty.

Wickes, H. W., Passed Assistant Surgeon. Granted leave of absence for ten days.

Fricks, L. D., Assistant Surgeon. Detailed as inspector of unserviceable property at Norfolk, Virginia.

Caminerio, H. S., Acting Assistant Surgeon. Detailed as quarantine officer for the port of Guantanamo, Cuba.

Promotion.

Thurston, E. J., to be hospital steward and chemist.

Board Convened.

Board convened to meet at the United States Marine Hospital, New York, at 10 o'clock A.M., August 16, 1899, for the physical examination of a candidate for appointment in the Revenue-Cutter Service. Detail for the Board: Stoner, George W., Surgeon, chairman; Hobdy, W. C., Assistant Surgeon; Billings, W. C., Assistant Surgeon, recorder.

Society Meetings for the Coming Week:

Monday, September 4th: New York Academy of Sciences (Section in Biology); Morrisania Medical Society, New York (private); Brooklyn Anatomical and Surgical Society (private); Corning, New York, Academy of Medicine; Utica, New York, Medical Library Association; St. Albans, Vermont, Medical Association; Providence, Rhode Island, Medical Association; Hartford, Connecticut, Medical Society; Chicago Medical Society.

Tuesday, September 5th: Buffalo Academy of Medicine (Section in Surgery); Elmira, New York, Academy of Medicine; Ogdensburg, New York, Medical Association; Syracuse, New York, Academy of Medicine; Medical Societies of the Counties of Franklin (quarterly), Herkimer (semi-annual), and Niagara (quarterly), New York; Hudson, New Jersey; County Medical Society (Jersey City); Androscoggin, Maine, County Medical Association (Lewiston); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore).

Wednesday, September 6th: New York Academy of Medicine (Section in Public Health); Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond, New York (New Brighton); Bridgeport, Connecticut, Medical Association.

Thursday, September 7th: New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, New York; Obstetrical Society of Philadelphia; Medical Society of City Hospital Alumni, of St. Louis; Atlantic Society of Medicine.

Friday, September 8th: Practitioners' Society of New York (private); Clinical Society of the New York Post-graduate Medical School and Hospital; Baltimore Clinical Society.

Saturday, September 9th: Manhattan Medical and Surgical Society, New York (private); Miller's River, Massachusetts, Medical Society.

BIRTHS, MARRIAGES, AND DEATHS.

Wilson—Lindsay.—In Boston, on Sunday, August 13th, Dr. Compton Wilson, United States Army, and Miss Jane Lindsay.

Died.

Linson.—In Tarrytown, New York, on Sunday, August 27th, Dr. John J. Lindsay, in the seventy-second year of his age.

McLeod.—In New York, on Wednesday, August 23d, Dr. Samuel Brown Wylie McLeod, in the sixtieth year of his age.

Schrenk.—In New York, on Sunday, August 30th, Dr. Andrew Schrenk.

Thorner.—In Avondale, Ohio, on Sunday, August 27th, Dr. Max Thorner, of Cincinnati.

SPECIAL ARTICLES.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By ARTHUR N. TAYLOR, LL.B.

CIVIL MALPRACTICE, INCLUDING GENERAL LIABILITY OF PHYSICIAN TO PATIENT.

(Continued from page 316.)

Liability for Presence of Unprofessional Attendant.

A peculiar case of liability arose a number of years ago in Michigan from an act which, although apparently done in good faith, was reprehensible indeed.

The evidence showed that a doctor who was sick and fatigued from overwork, and who was compelled to go a considerable distance over roads so bad that a horse could not be ridden or driven over them, to attend a case of confinement, secured the reluctant consent of a young unmarried man to attend him and assist in carrying his lantern, umbrella, and other articles necessary for the occasion, the night being dark and stormy. The plaintiff's house consisted of one room, with a bed, sink, or alcove, in front of which there was a curtain, and in which the doctor expected to find the patient. Upon arriving at the house the doctor told the husband he had brought a friend to help carry "his things." The husband said "All right," and invited them in and made no objection to the young man. Upon entering they found the patient in the main room, and it was there she was delivered of the child. The young
man conducted himself in a respectful manner, and ex-
cepting once, when called to hold the patient’s hand, 
while in a paroxysm of pain, sat facing the wall. Both 
the patient and her husband claimed they did not know 
the non-professional character of the young man, but 
supposed he was a physician or a student practising 
under the attending physician, and therefore made no 
objection to his presence.

In the trial court judgment was rendered for plain-
tiff, from which defendant took an appeal. Chief-Jus-
tice Marston, of the supreme court, in reviewing the 
case, said: “It would be shocking to our sense of right, 
 justice, and propriety to doubt even, but for such an 
act the law would afford an ample remedy. To the 
plaintiff the occasion was a most sacred one, and no one 
had a right to intrude unless invited, or because of 
some real and pressing necessity, which it is not pre-
tended existed in this case. The plaintiff had a legal 
right to the privacy of her apartment at such a time, 
and the law secures to her this right by requiring others 
to observe it, and to abstain from its violation. The 
fact that at the time she consented to the presence 
of the young man, supposing him to be a physician, does 
not preclude her from maintaining an action and re-
covering substantial damages upon afterward ascertain-
ing his true character. In obtaining admission at such 
a time and under such circumstances, without fully 
disclosing his true character, both parties were guilty of 
deceit, and the wrong thus done entitles the injured 
party to recover the damages afterward sustained, from 
shame and mortification upon discovering the true 
character of the defendants.”

Liability for Wrongful Certificate of Insanity—The duty 
which a physician is frequently called to perform, of 
passing upon the mental state of a fellow man, who, 
by virtue of his judgment, is either permitted to re-
main at large or is confined in a lunatic asylum, is a 
most grave and responsible one. An error of judgment 
may, on the one hand, mean a menace to the peace and 
even safety of the community, or, on the other hand, an 
unjust and lamentable deprivation of that most impor-
tant of all rights, personal liberty.

The purpose of the present examination of law is, 
however, to examine the physician’s liability for an 
improper exercise of these functions, and not the physi-
cian’s duties and obligations to society or to the person 
whose sanity is in question, except in so far as they 
affect the real subject of inquiry.

The method of determining the mental condition of 
one suspected of being insane is regulated in the several 
States by statutes differing somewhat in the different 
jurisdictions. A common method, however, of obtaining 
summary protection from the violence or possible vio-
ence of a lunatic is to confine him upon the certificate 
of usually two reputable physicians. What civil liabil-
ity the physician incurs who errs in making this cer-
tificate is the question to be considered.

The first step to be taken in passing upon the lia-
ibility of a physician is to determine whether or not the 
certificate is in itself correct or false. If the certificate 
is found to be correct, this, it seems, is a complete bar 
to a civil action against the physician for damages, for, 
in the absence of a statute imposing a penalty for a 
failure to comply with a certain method or mode of pro-
cedure in determining the mental condition of the party 
examined, the physician incurs no liability for the in-
efficiency of the modes which he pursued in reaching 
and certifying a correct conclusion.* Moreover, it has 
been held that the burden of proof is upon the plaintiff 
to show that at the time the certificate of insanity was 
given he was in fact sane, and that until this fact is 
shown by a preponderance of evidence the physician 
signing the certificate can not be held liable.†

It appearing that the certificate of insanity is in-
correct, and that the physicians have erred in their 
conclusion and certified to a condition which did not 
extist, does it then follow that a civil action for damages 
in favor of the person who has been wrongly imprisoned 
will lie against them? The answer to this question is 
practically the same as that which has been made to 
neary every question arising in the cases of malprac-
tice examined in these articles—viz., if the defendants 
were possessed of the ordinary amount of knowledge and 
skill which the law requires for the proper exercise of 
their duties, and if they used ordinary and reasonable 
care in making the examination and exercised their best 
judgment in determining the party’s mental condition, 
then they are not liable, whether their conclusion is cor-
rect or not. There is a prominent English case‡ in 
in which this question was passed upon and the law go-
verning the defendant’s liability lucidly and elaborately 
expounded by Justice Crompton in his instruction to 
the jury. The case is rather voluminous, covering over 
thirty pages in the volume of reports where it is record-
ed, yet a brief examination of the facts and the law 
which was held to be applicable will probably compen-
sate in enlightenment for the time required. The 
plaintiff was a shopkeeper in London, who lived very 
discordantly with his spouse—in fact, the want of do-

domestic harmony was frequently manifested in outbursts 
of violent temper, in which the use of abusive and ob-
scene epithets was common, and even physical violence 
to the wife’s person had been complained of. The plain-
tiff complained, among other things, of the wife’s ex-
travagance, and the evidence did show that she had 
taken articles from the shop and pawned them. The 
wife was accustomed to going to certain physicians with 
hers complaints regarding the husband’s treatment, 
among whom was one of the physicians who subsequently 
signed the certificate of lunacy. Upon one occasion 
when the husband met this physician and his wife to-
gether he made a remark which the physician construed 
as an imputation against the wife’s chastity, but which 
the husband apparently did not so intend. The wife also 
claimed that the husband slept with a drawn sword by his 
bed and that he repeatedly threatened her life. The de-
fendant in the case, together with the physician above 
referred to, perhaps from a desire to relieve the wife 
from the hardship of the husband’s persecutions, after a 
few minutes’ conversation held with him at different 
times, signed separate certificates of his insanity in 
which they respectively assigned the grounds for be-
lieving him insane, as follows:

First Certificate: 1. Facts indicating insanity ob-
erved by myself: He had a wild and staring look, with 
restless eyes and nervous, agitated manner. He repre-
sented to me that his wife was ruining himself and 
business, and he intimated that she was improperly 
associating with other men; he is evidently laboring 
under delusions, and he acts upon these delusions.

* DeMay vs. Roberts, 46 Mich., 190.
† Ibid.
‡ Hall vs. Semple, 3 F. and F., 337.
2. Other facts (if any) indicating insanity communicated to me by others.

He is guilty of repeated acts of violence; he constantly threatens his wife and often assaults her; he sleeps with a drawn sword by his bedside, and declares he will murder any one who approaches him, and he has often threatened to stab his wife.

The defendant who signed this certificate had not seen the sword at the time of certifying the plaintiff insane, but he afterward learned that the "drawn sword" was a theatrical or court dress sword.

Second Certificate: 1. Facts indicating insanity observed by myself: He had a restless, irritable, and excited manner, with a glaring look, and expressed much vindictiveness toward his wife, and said, "I must be a fool to mind what that woman has said." He said she had her fellows continually running after her, and intimated that I was one of them.

2. Other facts (if any) indicating insanity communicated to me by others:

On a former occasion, when I had called to see him, he had just before broken the looking glass to pieces, also the marble mantel and bedstead; he had been brandishing knives over his wife's head, and using horrid language, sometimes kicking her, tearing her bonnet and clothes off, and all without provocation, as I find from neighbors and old acquaintances that she is a discreet, sober, prudent, and patient woman.

This certificate was based upon an interview had more than seven days previously, and was accordingly, under the English statute, irregular, and of no effect. The plaintiff was released when the irregularity of the certificate was discovered, and he soon thereafter commenced suit against the defendant for damages.

The law which was held to govern in the case can probably be no better expressed than in the words of Justice Crompton taken from his charge to the jury. Therein the judge said: "Take me as saying to you in point of law that if a medical man assumes under this statute the duty of signing such a certificate, without making and by reason of his not making a due and proper examination, which a medical man under such circumstances ought to make and is called on to make, not in the exercise of extreme possible care, but in the exercise of ordinary care, so that he is guilty of culpable negligence, and damage ensues, then, that an action will lie, although there has been no spiteful or improper motive, and though the certificate is not false to his knowledge."

"The true ground of plaintiff's complaint is the negligence of the defendant, and the want of due care in the discharge of the duty thrown upon him; and I think that if a person assumes the duty of a medical man, under this statute, and signs a certificate of insanity which is untrue, without making the proper examination and inquiries which the circumstances of the case would require from a medical man using proper skill in such a matter, if he states that which is untrue and damage ensues to the party thereby, he is liable to an action, and it is to that I desire to call your particular attention. It is not that a medical man is bound to form a right judgment so as to be liable to an action if he does not. There are cases of insanity which are very difficult to deal with or to understand. But what he is required to do is to make an examination, and, if it be necessary, to make such inquiries as may be required. It would be unjust if a man were to be visited, in cases of this kind, with consequences arising from mere error of judgment or mistake of fact.

"There must be, to make him liable, negligence in the discharge of those proper duties which it must be taken he has assumed in undertaking to sign the certificate of insanity, and if you are satisfied that there has been negligence with reference to these matters—culpable negligence, as I have described—then he is liable. Now, I can not help thinking in a matter of this kind, which is not like a mere preliminary inquiry before a magistrate, but a proceeding upon which a man is to be at once confined to imprisonment as a lunatic, very considerable care is necessary. One can hardly say precisely what that degree of care may be. It is said that one man may be satisfied with a quicker examination than another. We, for instance, would take a long time before we should be able to form a judgment in a matter of this kind. A person experienced in such matters might decide more quickly, while an ordinary medical practitioner might require a longer time. We take it as clear, however, that considerable care ought to be used."

The jury in this case rendered a verdict for the plaintiff, assessing his damages at one hundred and fifty pounds.

The principles which were held to govern in the English case have been accepted as the law by American courts whenever this question has arisen, and will undoubtedly continue to be so accepted. Therefore, as long as the physician possesses proper knowledge and science and conducts the examination with reasonable and ordinary care the result of his conclusion will never despoil his estate, even though in the exercise of his best judgment he may have been in error.

Other cases might be shown to illustrate, possibly more fully, the application of the principles, but it is thought that further elaboration will be superfluous.

(To be continued.)

Pith of Current Literature.

The Internal Administration of Urotropine to Destroy Infectiousness of Typhoid Urine.—The Montreal Medical Journal for August, in an editorial On the Infectiousness of Typhoid Excreta, says that we have to recognize that it is in the late stages of the disease that the urine may be infectious and that this infection may continue far into convalescence. In one case Petruhsky found the enormous number of a hundred and seventy-two million bacilli in each cubic centimetre of urine. Indeed, as Horton-Smith points out, the wide contamination of extensive sources of water supply is more easily explicable by means of this infected urine than by the faeces.

It would seem, says the Journal, almost impossible to lay down strict rules with regard to the disposal of the urine of those who regard themselves in complete health; it is, however, possible for the physician to order that, until the very last day of their confinement as patients, the urine of those suffering from typhoid should be disinfect; beyond this point it is practically impossible to

lay down any rule. Happily, there is still another way out of this difficulty. Richardson (Journal of Experimental Medicine, 1899, vol. iv, p. 1) has proved very clearly that the administration of ten grains of urotropine three times a day leads to the rapid disappearance of the bacilli from the urine. In one case in St. Bartholomew’s, under Dr. Gee and Dr. Andrews, treatment for three days with salol had no effect, the typhoid bacilli remaining present in enormous numbers in the urine; when urotropine was given as above, at the end of forty-eight hours the urine became and remained henceforth absolutely sterile.

Thus, the Journal says, we may well recommend with Richardson and Horton-Smith that all typhoid patients be given small doses of urotropine, commencing with the third week of the disease.

The Relation of Wines to Rheumatism and Gout.—Dr. P. C. Redmondino (Pacific Medical Journal, August), in a paper on Wine and Gout, says that from experience and observation, as well as comparisons, he has come to look upon light beers, light wines, and even dry champagne, when partaken of judiciously and in moderation, as being the very opposite of injurious in either gout or rheumatism; in fact, were the moral restrictions cast about wine drinking at meals and the seeming immorality or wickedness of the practice removed from the mind and from our customs so that our table habits would more resemble those of the temperate Latin and Teutonic countries of Europe, he is satisfied that there would be less dyspepsia and less rheumatism, as well as much less of the many and various neurotic ailments which in these American climates take the place of gout.

Disease statistics show that among the Germans who indulge habitually in small beers, as well as among the inhabitants of the Rhine and Mosel wine districts where the average man drinks at least from one to two quarts of beer or a bottle of wine daily, gout and its cousin, rheumatism, exist in a greatly diminished ratio.

Great care must, however, he says, be taken that only light, dry wines are used. Many of our California wines, besides being heavily alcoholic, are also very injuriously sweet. To this category belong most of our muscatels, our sherries, and our ports, which in their natural state greatly resemble the heavy Portuguese or Spanish wines to whose use England largely owes its quota of gout; a disease which was rare in England previous to the date of the exclusion of the light wines of France by the working of the Methuen Treaty of 1703, during the reign of Queen Anne, which replaced the former light table wines of France by the heavy and reenforced wines of Portugal and Spain, a change which not only inflicted the gout upon hapless England, but also brought to that nation the largest quota of its intemperance, much of the resulting difficulties, moral and physical, being due to the change in the wines induced by the reenforcing or fortifying deemed necessary for the transportation of the wine; for in Spain or Portugal, where these wines are drunk in their unfortified condition, neither drunkenness nor gout is observed as a result of their consumption. It is from this fortification with alcohols of doubtful sources and greatly varying in their effect upon man that much harm results, as the fortification is not always performed with alcohol made from wine that is pressed from the grape, carefully collected statistics made in France showing that consumers of spirited liquors distilled from the grape largely escape the direful effects of delirium tremens as well as the transmission of hereditary degenerations resulting from alcoholic overindulgence, in comparison with those who indulge in alcoholic liquors produced by distillation from pears, potatoes, or rice.

One Hundred and Thirty-two Gallstones removed without Operation.—Dr. Edward Spiedel (American Practitioner and News, July 1st) records the case of a lady, fifty-five years of age, who suffered severely from gallstones, and who first consulted him on September 17, 1898. The treatment consisted of a calomel purge followed by a saline. Three glasses of buttermilk daily were ordered, the quantity to be increased to five. The patient became accustomed to it. Hot baths at bedtime were ordered twice weekly, and three times weekly a high rectal enema of normal saline solution at a temperature of from 110° to 120° F.

For the attacks of colic the patient was given a mixture containing two grains and a half each of antipyrine and phenocoll muritate to the dose, such a dose to be taken every half hour with hot water until relieved, the hot bath and rectal injection being used at the time also. In the interval the patient was put upon ten grains of salicylate of strontium three times daily. During the last two months the medication consisted of increasing doses of tincture of Chionanthus virginica, the prescription being varied by the addition at times of one of the tonic bitters, as nux vomica and calumba, again by the addition of arsenite of copper, and in the last month by the administration of nitro-muriatic acid with the chionanthus.

The patient improved gradually under treatment, the attacks of colic becoming shorter and less frequent.
